Preface

With its 15th edition, the International Conference of the Learning Sciences (ICLS) has moved to being celebrated annually. Together with the International Conference of Computer-Supported Collaborative Learning (CSCL), it is part of the 2021 Annual Meeting of the International Society of the Learning Sciences.

As the first of its kind, the ISLS Annual Meeting 2021 is a milestone in the evolution of the Learning Sciences community. This meeting was envisaged to take place in Bochum, a location with a history that symbolizes the theme of the conference: Reflecting the past and embracing the future. Bochum lies in the heart of Europe in a region that has been historically shaped by the heavy industries but also by the solidarity and conviviality of workers with a variety of cultural backgrounds. After the decay of the old industries, this spirit of solidarity has become an important asset for embracing the present and future challenges. We hope this will inspire our growing international community, even though we do not have a chance to meet in place this time.

As part of the ISLS Annual Meeting, ICLS 2021 invited academics, researchers, professionals, and educators to share and embrace their diverse views with empirical, theoretical, conceptual, and design-based work. All papers, posters, and symposia were subject to a double-blind peer review. In total, 34% (62 out of 183) of long paper submissions, and 27% (40 out of 146) of short paper submissions were accepted in the category where they were submitted. In addition, a number of submissions were accepted in another category (short papers or posters). As a result, the ICLS Proceedings features 62 long papers, 72 short papers (work-in-progress), 153 posters, and nine symposia, with contributions coming from four continents: Asia, Europe, North America, and South America.

The content of the LS track covers a number of exciting contemporaneous topics, including computational thinking, teacher practices, STEM education, design-based implementation research, game-based learning, data visualization, epistemic practices, learning in virtual environments, equity and justice, knowledge building, emotions, and much more. We are proud of the way that scholarship within the learning sciences community reflects and explores the realities of our everyday world with an eye on making it a better place to live.

We would like to take this opportunity to offer a special thank you to the 315 reviewers who carried out over 1000 reviews, the 86 senior reviewers who greatly helped us in making the final decisions on each submission, as well as the numerous people around the process who have spent countless hours ensuring that the program is of high quality.

It is a great honor to edit this year's proceedings for the Learning Sciences community in ISLS. We hope all of you enjoy your participation in the conference and social activities designed online.

Erica de Vries, Yotam Hod, June Ahn
ICLS 2021 Conference Program Co-chairs

Acknowledgments

ISLS Annual Meeting 2021 conference organizers would like to give special thanks to the following committees and people for their support:

- International Society of the Learning Sciences (ISLS)
- ISLS Board of Directors and Executive Committee
- Ruhr University Bochum, Germany
- Deutsche Forschungsgemeinschaft (DFG)
- Wallace Foundation
- National Science Foundation (NSF)
- ExOrdo Support Team
- Whova Support Team
- Gather/Meetingland Support Team
- Conference Organizing Committee including
    - LS and CSCL Program Committees
    - Social Media Communications Co-Chairs
    - Doctoral Consortium Co-Chairs
    - Early Career Workshop Co-Chairs
    - Mid-Career Workshop Co-Chairs
    - Interactive Tools and Demos Co-Chairs
    - Pre-Conference Workshops and Tutorials Co-Chairs
    - Technology Support Committee
    - Online Conference Committee
    - ISLS 2021 Advisory Board
- Reviewers and Sr. Reviewers
- Best Paper Award Committees

Visual Cues in a Video-Based Learning Environment: The Role of Prior Knowledge and its Effects on Eye Movement Measures

Abstract: This study examined the effect of prior knowledge on students' gaze behavior while studying in a video-based learning environment. A total of 23 participants took part in a lesson about electric circuits. Their learning was accompanied by visual cues that served as written explanations in boxes with arrows. The results showed (1) differences in cue utilization and the amount of visual attention on cued parts depending on different levels of prior knowledge, and (2) varying gaze patterns between experts and novices. Although both prior knowledge groups made use of the visual cues, they probably had different functions for them. In light of these variations, recommendations as a result are made for complex video-based learning that is accompanied by visual cues.

Keywords: multimedia, visual cues, prior knowledge, eye-tracking, gaze pattern

Introduction

Computer-based learning environments have become an important educational element. Digital instruction is on the rise, and in some cases is even replacing conventional schooling. This technology offers various multimedia learning opportunities that combine text and pictures (Mayer, 2014).

Combinations of external representations (e.g. graphics combined with textual information) can be beneficial for learning (Ainsworth, 2006). When learners work for instance with complex content having high element interactivity (e.g. electric circuit diagrams), additional external representations (e.g. instructional cues) are often necessary for understanding or solving tasks (e.g. Ertl et al., 2006; Suthers & Hundhausen, 2003). Computer-based learning environments such as videos or animations are a useful tool for implementing different ways of instructional support.

Learning with additional external support

Instructional (e.g. verbal- or text-based) cues help organize learning material content, and can emphasize the relationship between content-related aspects (de Koning et al., 2009). According to the signaling or cueing principle (van Gog, 2014), cues also help draw learners' attention to task-relevant information in a presentation. Cues furthermore help reduce visual searches within learning material (Chandler & Sweller, 1991) and guide learners' information processing (de Koning et al., 2009). They also assist learners who on their own might have difficulty identifying essential information (Alpizar et al., 2020).

The positive effect of cueing has been extensively examined, and is supported by several meta-analyses (Alpizar et al., 2020; Richter et al., 2016; Schneider et al., 2018). In particular, learners with low prior knowledge benefit from instructional support (e.g. Alpizar et al., 2020). Some studies (e.g. Richter et al., 2016, 2018) have contrastingly reported negative effects for learners with a high level of prior knowledge. This effect is known as the *expertise reversal effect* (Kalyuga, 2014) and suggests that additional aids obstruct the learning process because they present redundant content that is already known (Kalyuga, 2009; Kalyuga et al., 2003). In other words, the same information presented in multiple modalities is redundant for learners possessing high prior knowledge (Kalyuga, 2009), and imposes incremental processing of unnecessary materials (Kalyuga et al., 2003). Richter and colleagues (2018) pointed out that learners usually process both sources of information while learning with multimedia (i.e. text and pictures). This is supported by an instructional format where information is physically integrated (e.g. text is embedded within a picture) where attention does not have to be divided. Learners with low prior knowledge will benefit from this kind of instructional format because they do not need additional working memory resources for mental integration (Ayres & Sweller, 2014). In contrast, learners with high prior knowledge will be forced to process information that is likely to be redundant (Kalyuga et al., 1998).

Prior knowledge and its effect on visual attention

The effect of prior knowledge on visual attention is frequently discussed in multimedia research. According to the redundancy principle of multimedia learning, Richter et al. (2018) noticed that learners with high levels of expertise are unable to disregard redundant information. Other studies have however shown that skilled learners were in fact able to ignore irrelevant information and focus on the elements at hand (e.g. Jarodzka et al., 2010). According to the information-reduction hypothesis by Haider and Frensch (1999, p. 172), learners with a higher level of expertise are able "to become selective in their use of information, that is, to distinguish between task-relevant and task-redundant information." The authors pointed out that "redundant information is perceptually ignored whenever this is possible" (p. 188). This information-reduction process consists of two steps. First, learners basically identify task-relevant and task-redundant information. Second, they actively select and process task-relevant information, while neglecting unnecessary information thanks to strategic considerations based on practice.

As seen here, prior knowledge affects visual attention. In their meta-analysis, Gegenfurtner and colleagues (2011) examined different levels of prior knowledge and its effect on the visual attention of learners working with visual representations. For instance, they found that learners with a higher level of expertise experienced longer fixation durations on relevant areas, and expressed longer saccades. Similarly, in the domain of natural science, when working with external visual representations, novices relied more than experts on different visual features of the representations to guide their understanding (e.g. Lowe, 2003). Some of these findings were obtained using eye-tracking technology.

Eye-tracking to understand visual attention in learning

Eye-tracking has in recent years become an important tool for analyzing learning processes in educational science (Jarodzka et al., 2017). This technology provides information about learners' perceptions and interests in visual stimuli (Duchowski, 2003). Eye-tracking is furthermore used to optimize multimedia learning environments. Numerous studies have analyzed the visual attention determined by eye-tracking technology to understand cognitive processes such as selecting, organizing, and integrating while learning with multimedia (see Alemdag & Cagiltay, 2018 for an overview).

Key types of eye-movement measures included fixations and saccades (van Gog & Jarodzka, 2013). These are gathered on temporal, spatial, and count scales, and serve as reliable indicators of cognitive learning processes (Lai et al., 2013). Fixation duration and fixation counts generally display the amount of attention allocated to visual representations (Scheiter & Eitel, 2017). Longer fixation durations can report the depth of processing (Rayner, 1998), whereas a higher number of fixations can represent a measure of processing intensity (Glaser & Schwan, 2015). Saccades show learners' perceptual transitions between different external representations, and reveal the integration process (Scheiter & Eitel, 2017). Scan paths quantitatively allow successive fixation positions to be examined, and demonstrate attention sequences. So, these kinds of gaze parameters can provide insight into learning behavior, most notably while learning with visual cues.

Research questions

Generally positive effects of cueing on learning outcomes have been determined (e.g. Richter et al., 2016; Schneider et al., 2018). Based on these findings, our research interest is not on learning outcomes per se, but instead on further investigating the learning behavior of persons with different levels of prior knowledge as they learn with visual cues. Alemdag and Cagiltay (2018) in their study incorporated qualitative analyses obtained from measurements of scan paths. The present research contributes to understanding individual learning behavior while dealing with visual cues, and also aims to optimize computer-based learning environments. This study will additionally contribute to qualitative research on scan paths.

RQ1: *To what extent do people with high and low prior knowledge differ in their use of visual cues?*
Learners with low prior knowledge are likely to revisit visual cues more often than learners with high prior knowledge because they experience the cues as helpful in learning more effectively (cf. the signaling or cueing principle). Learners with high prior knowledge in turn might experience some of the cues as redundant, and as a result revisit the visual cues less frequently (cf. the redundancy effect).
RQ2: *To what extent do people with high and low prior knowledge differ in their visual attention to the cued parts?*
Learners with high prior knowledge are able to devote more attention to cued four electric circuits than learners with low prior knowledge (e.g. Jarodzka et al., 2010).
RQ3: *What differences occur in the gaze pattern of learners with high prior knowledge and low cue utilization (experts) compared to learners with low prior knowledge and high cue utilization (novices)?*

According to the information reduction hypothesis (Haider & Frensch, 1999), learners with high prior knowledge and low cue utilization are more selective in their information processing, and differentiate between task-relevant and task-redundant information.

Method

The data in this study was collected as part of a larger experiment (Ertl et al., 2020). Based on our research interest, we only focused on specific variables to investigate the role of prior knowledge during studying with visual cues in a complex physics learning environment. Twenty-three students from a German university participated in the computer-based experiment. The six female and 17 male participants were between 20 and 30 years old, and had a mean age of 22.34 (SD = 2.55). The participation was voluntary and rewarded with a €10.00 voucher or one course credit.

Procedure

Participants were tested during an individual session by a professional examiner. Before starting, every participant generated a personal code and completed a survey including their age and gender. The session lasted about sixty minutes and included both a pre- and post-test.

Prior to the experiment, participants were asked about their task-specific prior knowledge regarding the components of electrical circuits. This was followed by two learning phases: First, the participants refreshed their knowledge about electrical circuit symbols (e.g. switch or light source) with the help of illustrations. Second, they watched eight time-limited videos consisting of a task and four electrical circuits each. Some tasks added an additional electrical circuit (i.e. reference circuit) which was also accompanied by cues (i.e. reference cues). In this phase, participants applied physical concepts (application tasks) or a given electrical circuit (i.e. reference circuit) to identify an equivalent electrical circuit (comparison tasks). They obtained system-paced cues as external representational guidance in the learning material. These were presented as on-screen texts in boxes. The text boxes had arrows pointing to the corresponding object being explained (see Figure 1). The cues introduced the components of each electric circuit presented and their types of connections (serial vs. parallel).

Eye-tracking data was collected during the second phase of learning by using the SMI RED eye-tracker. Learners sat in front of a notebook with a 15” screen at a distance of about 60 cm. Their eye movements were recorded contact-free with a calibrated infrared sensor placed on the notebook. The participants then completed a test consisting of recall and transfer tasks.

Measures

Prior knowledge (pre-test) was scored on six self-constructed items (Cronbach’s α = .87). Elements of the electric circuits presented later were shown, and participants were asked to identify them. All six prior knowledge items were added to obtain a score between 0 to 6 points, indicating their overall prior knowledge of electric circuits. We then divided the participants into groups: low prior knowledge (between 0 and 3 points; 10 participants) and high prior knowledge (between 4 and 6 points; 13 participants).

Cue utilization (Eye movement measure) was operationalized as revisits to visual cues in the second learning phase. Revisits indicated how many times participants re-fixated on visual cues when they needed additional information. A revisit was counted when a fixation landed on the area of interest (AOI). To measure cue utilization, we first pre-defined an AOI for each cue of the eight learning tasks. Afterwards, we summed up all revisits to the overall 51 cues (Cronbach’s α = .92).

Visual attention (Eye movement measure) was measured during the second learning phase. We used a mixed-method approach to examine the attention allocation to the cued parts. Quantitatively, the distribution of visual attention over all cued electric circuits was expressed by the average fixation duration (Cronbach’s α = .87). First, eight AOIs were pre-defined, which consisted of the four circuits per task. The total number of fixations and the fixation time on each AOI were then calculated. The sum of total fixation times was divided by the number of all fixations, which resulted in the average fixation duration (in milliseconds). Scan paths were quantitatively used to show visual attention.

Results

SPSS Statistics version 26 was used for all analyses, with a pre-defined α-level of .05 for inference testing. All preconditions for statistical analyses were additionally tested and confirmed.

Treatment check. Figure 1 provides a scan path of a sequence of four images to show how the intervention was implemented. Furthermore, a qualitative analysis of all gaze behavior during the presentation of visual cues was conducted to examine whether the desired effect of attentional guidance was achieved. The sequence exemplarily shows the effect of cueing. Overall, the visual cues were utilized, guiding the learners’ core attention to the elements in the electrical circuits referenced in the cue.

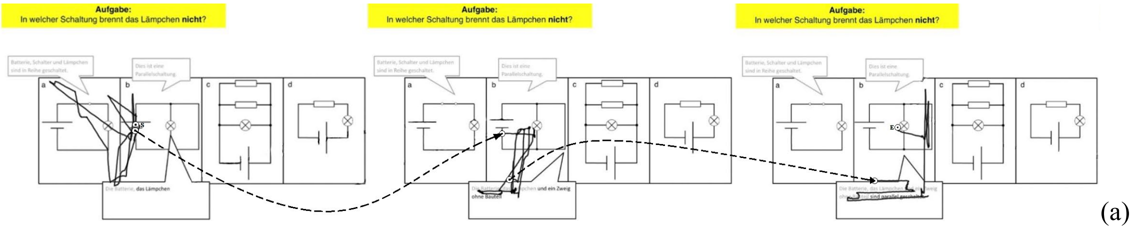

Figure 1. An exemplary sequence (a-c) during a presentation of a visual cue to show utilization and its effect on directing attention. Each panel demonstrates three seconds that confronted learners with cues.

RQ1: Differences in visual cue utilization

An ANOVA with high and low prior knowledge as the between-subjects factor, and number of revisits as dependent variable was conducted to examine the differences in cue utilization. No significant effect was found for the different levels of prior knowledge on cue utilization. The results merely indicated a statistical tendency towards lower cue utilization by high prior knowledge learners, $F(1, 21) = 2.99$, $p = .099$, $\eta_p^2 = .13$.

A MANOVA was additionally conducted with high and low prior knowledge as the between-subjects factor and revisits of visual cues in each task as dependent variables. The results revealed consistent differences between learners with high and low prior knowledge on cue utilization, as shown in Figure 2. A significant effect of prior knowledge on cue utilization was only found in Task 5.

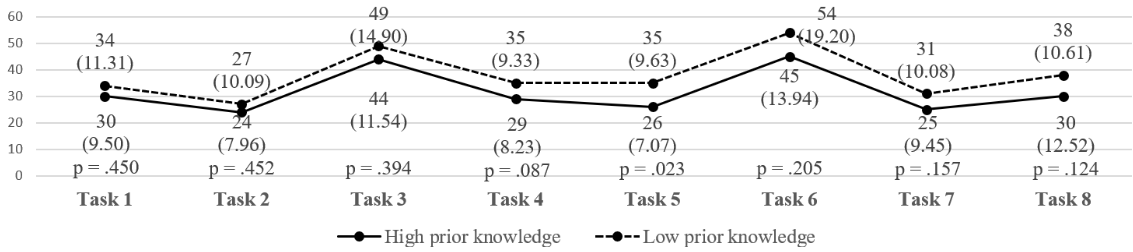

Figure 2. Mean values of the revisits on visual cues for high and low prior knowledge. The second number in parentheses indicates the standard deviation (SD).

RQ2: Differences in attention allocation on cued parts

An ANOVA was conducted with high and low prior knowledge as the between-subjects factor, and average fixation duration as dependent variable to investigate the differences in attention allocation on the cued parts across the eight tasks. A significant effect of prior knowledge was found for average fixation duration on different tasks, which indicates higher visual attention of learners with high prior knowledge, $F(1, 21)= 4.56$, $p = .045$, $\eta_p^2 = .18$.

In addition, a MANOVA was conducted with high and low prior knowledge as the between-subjects factor and the average fixation duration for each task as dependent variables. The results revealed consistent differences between learners with high and low prior knowledge of the cued parts, as shown in Figure 3. Significant effects of prior knowledge on average fixation duration were however only found for the first three tasks.

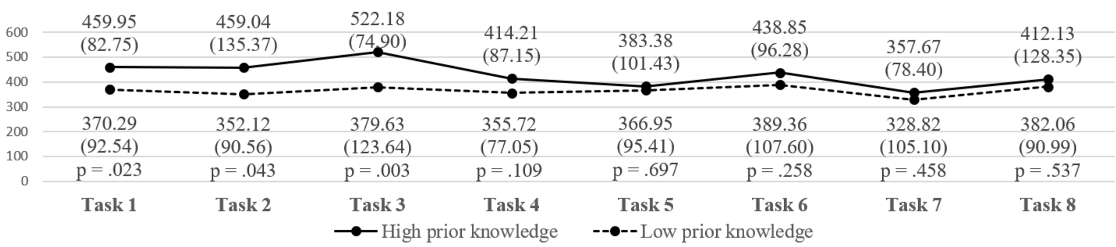

Figure 3. Mean values of visual attention in milliseconds on cued parts for high and low prior knowledge. The second number in parentheses indicates the standard deviation (SD).

RQ3: Differences in gaze pattern

A qualitative analysis of scan paths was conducted to investigate the gaze pattern of learners who differ in levels of prior knowledge and cue utilization. First, we split students based on their cue utilization into three groups using terciles. To analyze gaze patterns, we exemplarily selected one typical gaze pattern from learners of the lower and upper third (see Figures 4-5) as representatives of high and low cue utilization. We then analyzed ten-second sequences of their gaze patterns during two types of tasks: application tasks applying physical concepts, and comparison tasks using an additionally provided electrical circuit.

Application task. The focus on the learner with high cue utilization and low prior knowledge (Panels 1a-1c) was more directed to the cues and electrical circuits being described. Here the learner repeatedly jumped back to the cue presented, as indicated by vertical saccades between the visual cue and cued elements (Panels 1a-1c, A). In addition, the learner also jumped back to a cue which had already been presented (Panel 1c, B).

In comparison, the gaze behavior of the learner with low cue utilization and high prior knowledge (Panels 2a-2c) was initially scattered. First, the learner scanned all presented circuits and compared them with each other (Panels 2a-2b, C), as indicated by horizontal saccades between the four electric circuits. Later on, the learner fixated on the visual cue and did not frequently or repeatedly jump back to the cue presented (Panel 2c, D).

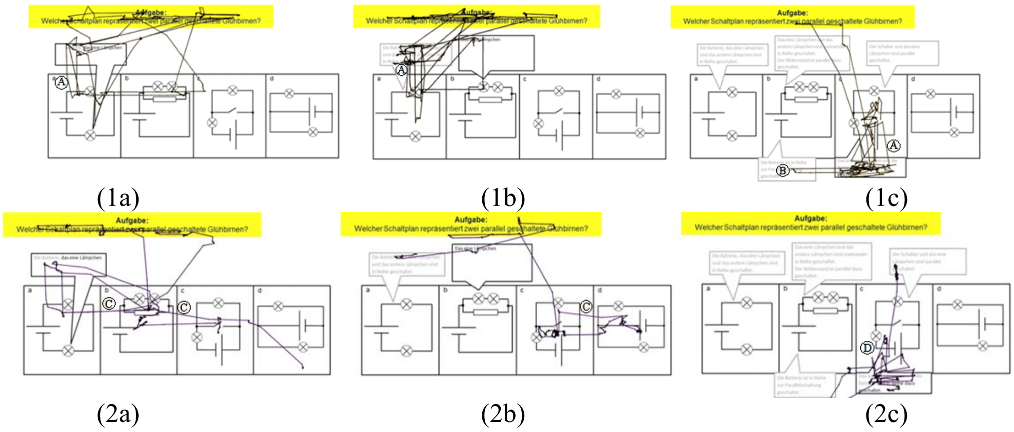

Figure 4. Ten-second sequences of gaze behavior during an application task. Panels 1a-1c show a common gaze pattern of a learner with high cue utilization and low prior knowledge. Panels 2a-2c show a common gaze pattern of a learner with low cue utilization and high prior knowledge.

Comparison task. Two cues were sequentially provided in Panels 3a and 4a over a span of ten seconds, i.e. the second part of the reference cue on the left (3a, E) and the first part of the cue to circuit (3a, F). In general, the focus of the learner with high cue utilization and low prior knowledge (Panels 3a-3c) was directed more to the cues as well as the electrical circuits being described. The learner also jumped back to the reference cue on the right, which had already been presented (Panel 3a, G). Furthermore, the learner repeatedly jumped back to the cue presented (e.g. Panels 3b-3c, H), as indicated by vertical saccades between the visual cue and the physics elements.

In comparison, the gaze behavior of the learner with low cue utilization and high prior knowledge (Panels 4a-4c) was initially scattered. Here the learner scanned all four presented circuits and compared them with each other (note the forward and backward jumps between the electric circuits, regardless of the cue being discussed (4a, I)). Later on, the learner also fixated on the visual cue, but did not often jump back to the cue presented (4b-4c, J).

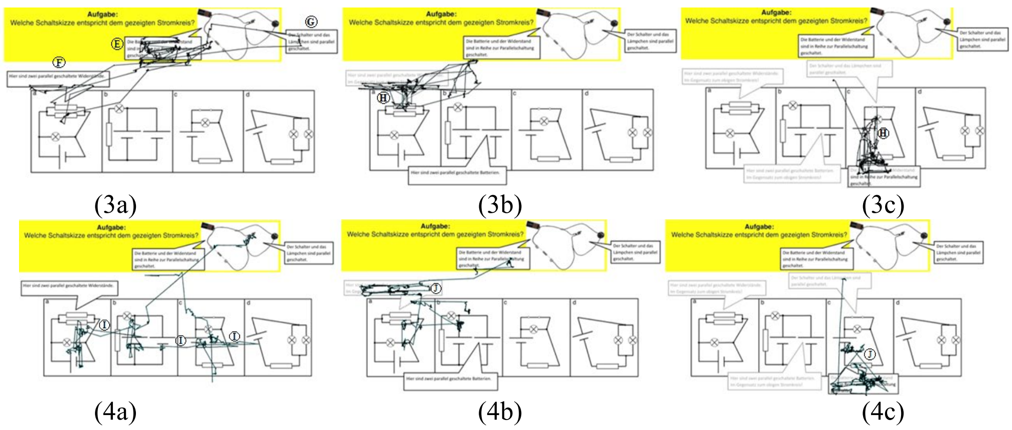

Figure 5. Ten-second sequences of gaze behavior during a comparison task. Panels 3a-3c show a common gaze pattern of a learner with a high cue utilization and low prior knowledge. Panels 4a-4c show a common gaze pattern of a learner with a low cue utilization and high prior knowledge.

General discussion

This study aimed to identify effects of prior knowledge on learning behavior while dealing with visual cues in a video-based learning environment of electric circuits. Although we found consistent differences between prior knowledge groups across the eight tasks, there was no significant difference between high and low prior knowledge learners with regard to their use of visual cues, even though there was a significant difference of average fixation duration on the cued parts. In addition, a distinct influence of prior knowledge on gaze behavior in perceiving two different types of tasks was qualitatively found.

According to the cueing or signaling principle (van Gog, 2014) and the redundancy effect (Kalyuga, 2009), we assumed that learners with low prior knowledge would be more likely to revisit visual cues than high prior knowledge learners. The consistent differences over all eight tasks between the groups may suggest that learners with low prior knowledge need more instructional guidance when dealing with schematic diagrams such as electrical circuits, whereas visual cues could be redundant for some high prior knowledge learners. Hegarty and colleagues (1991) stated that learners generally have difficulties interpreting schematic diagrams. This phenomenon might explain why it was difficult to find a significant difference in cue utilization between the two groups.

Furthermore, we could support our hypothesis that high prior knowledge learners were better able to devote their attention to the cued parts than low prior knowledge learners (Jarodzka et al., 2010). Our assumption was that learners with high prior knowledge would not lack information given in the visual cues, and could therefore spend more cognitive resources on active problem solving; they focused longer on the cued parts, which were the relevant areas for understanding the tasks. The result of longer fixation durations on the cued parts of learners with high prior knowledge is in line with the findings by Gegenfurtner and colleagues (2011). Our result is in turn closely related to our first finding of a smaller number of revisits to visual cues. A deeper focus on visual cues could potentially achieve a lower average fixation duration on the cued parts. When learners frequently revisit cues, especially in a system-paced format, study time might be lost for the cued parts, i.e. for areas relevant for understanding and solving the task. Thus, low prior knowledge learners in our study had less time to focus more deeply on the cued parts.

According to the information-reduction hypothesis by Haider and Frensch (1999), we assumed that high prior knowledge learners would be more selective in their information processing, differentiating between task-relevant and task-redundant information. Via qualitative scan paths analysis, we were able to support these assumptions for both types of tasks. In line with Gegenfurtner and colleagues (2011), higher expertise learners displayed longer saccades on the visualizations of the electrical circuits. This gaze pattern was often found at the beginning. They initially scanned the four electric circuits before focusing more deeply on information perhaps identified as task-relevant. This finding is consistent with the first step of the information-reduction process suggested by Haider and Frensch (1999). In the further course, learners with high prior knowledge fixed onto visual cues. With regard to the second step of the information-reduction process, high prior knowledge learners might aim to identify the visualizations of electrical circuits as redundant. This assumption appears consistent with previous studies (e.g. Jarodzka et al., 2010) where high prior knowledge learners were better able to ignore redundant elements. Their gaze pattern showed that they did not permanently try to focus on both information sources (i.e. cues and electrical circuits). In addition, it seems that they preferred learning with visual cues. One explanation for this might lie in the construction of coherent mental representations of the different electrical circuits. Due to their higher level of expertise, these learners are able to create the mental models they require for the task at hand while reading the written explanations in the cues. This assumption is supported by text processing research (e.g. Kintsch & van Dijk, 1978) which empirically shows that readers construct coherent mental models of texts (e.g. Myers et al., 1994). In addition, it might be that these learners expected new information to be provided they did not previously know. Perhaps they reviewed their body of knowledge and tried probably filling knowledge gaps while learning mostly with visual cues.

In sum, the qualitative results showed that high prior knowledge learners as well as low prior knowledge learners used the visual cues. Along with the quantitative results, we can also derive from the qualitative results that learners with low prior knowledge needed more visual cues when learning with different electrical circuits, as indicated by numerous vertical saccades between the visual cues and the corresponding elements. Low prior knowledge learners mostly fixated on the visual cues at the beginning of the presentation, suggesting their need for instructional guidance.

Limitations

This study is not without limitations. Its sample size of 23 participants is rather small, providing only low statistical power. And small, albeit remarkable effects identified within it were not significant. Eye tracking studies are in fact typically conducted with a low number of participants (Gegenfurtner et al., 2011) due to the time-consuming generation of each participant's eye-tracking data. They moreover require special hardware equipment and software, which limits the number of possible participants.

A further limitation is the restricted analysis of eye tracking parameters to investigate cue utilization. Visual cues generate additional gaze behavior, a natural result of having to read written explanations. Therefore, we only focused on the parameter of eye movement revisits on AOI, which were not directly influenced by reading skills.

Conclusion and implications

Although both high prior knowledge learners and low prior knowledge learners alike used the visual cues in this study, each group applied them differently. On the basis of the mixed-method approach, and with regard to the different levels of prior knowledge, our findings identified two different functions of visual cues. For learners with low prior knowledge, visual cues offer additional support, providing lacking information and guiding learners through complex tasks. For learners with high prior knowledge, the information in the visual cues offers the opportunity to control or check their knowledge. Cues also appeared helpful for both expertise groups. We suggest that future research should use mixed-method approaches to gain deeper and various insights into learning behavior that extend beyond statistical findings.

In terms of the different levels of expertise, practical implications for using visual cues in a computer-based learning environment can be drawn from this study. Complex computer-based learning environments should be individualized to the different levels of expertise. A learning environment offering a self-paced format to sufficiently study the instructional support and relevant areas for understanding and solving the tasks might benefit low prior knowledge learners. Learners with high prior knowledge seem to prefer working with visual cues. Learning environments should basically offer the opportunity to display cues for high prior knowledge learners. More research is however needed to understand the use of visual cues for learners of high expertise.

University of Colorado Boulder

Abstract: We facilitated a remote educational summer camp for teenage youth, with participants "sheltering in place" at home due to the COVID-19 pandemic. The summer camp was part of an initiative aimed at promoting STEM education for youth through learning about their pets' senses and engaging in a co-design project to enrich aspects of their pets' lives. We describe how situating scientific and design activities within the home and with pets engages participants in ethnomethodological practices such as field work, naturalistic observation, and in situ design that build upon their funds of knowledge. We discuss implications for the designs of learning environments that leverage the benefits of at-home science and design with pets.

Introduction

As part of a larger project (Kelly et al., 2020), we planned to hold a summer camp for teenage youth to engage adolescents and their pets in feminist-oriented science, design, and engineering during the summer of 2020. Due to the COVID-19 pandemic, we were forced to run the entire program with facilitators and participants staying in their homes. We designed the camp to make the most of participants' time at home with their pets and connect empathetic practices to engagement into science and engineering practices (National Research Council, 2012; NGSS Lead States, 2013). We structured the camp to engage participants to learn about their pets' senses and experiences at home, and to engage participants in week-long co-design projects with the goal of enriching their own pets' lives. Drawing inspiration from Hollan and Stornetta's (1992) paper on how researchers and designers should leave behind notions of simply using telecommunication to recreate the experience of "being there," we use this experience created by circumstance to examine aspects of location, timing, and mode in learning environment design that may be useful well beyond the pandemic. We present the design of our remote summer camp, identify several key advantages of this type of learning environment, and summarize implications for the learning sciences community

Camp design

Theoretical and conceptual background

Researchers have taken different approaches to the ways in which homes, classrooms, and other spaces can support learning. Learning environment design in both informal and formal settings tends to aim towards physically co-located and synchronous facilitation when possible, increasingly with CSCL tools to mediate productive interaction, shared inscriptions, and records (Tissenbaum & Slotta, 2019). Exceptions to co-location in formal and informal education programs tend to occur when participants are geographically distributed and cannot travel to be together, and exceptions to synchronous tend to be when time is desired for individual preparation, practice, or reinforcement, as in flipped classrooms (Akçayır & Akçayır, 2018), or when time is desired for reflection and development of products. Connected learning acknowledges that learning happens across spaces and relationships in people's lives (Ito et al., 2013, 2020). Oftentimes, the home is still a proxy of connected learning for further activities that are done in the classroom. In our work, we directly situate the scientific inquiry and discovery in the home. The usual preference for in-class learning over at-home learning limits opportunities for students' home-based funds of knowledge to inform, motivate, and contextualize learning (Moll et al., 1992). Rather than simply recreating the same kinds of in-class experiences with Zoom and other media spaces for collaboration, we aimed to go "beyond being there" and designed situated learning experiences that would take place within the context (including physical affordances and relations with other actors) of youths' homes (Gaver, 1992; Hollan & Stornetta, 1992). "Activity and setting are seen as mutually crafting" (Lave, 1982, p. 6). Situating scientific and engineering problems within youths' homes with their pets establishes students as independent researchers, and more importantly, as experts, as they can draw on their direct experience and prior knowledge of their pets. We aimed to create at-home activities ("homework"), but not in the traditional sense of homework that is done to reinforce or expand upon learning done in the classroom (Carr, 2013), but as ethnomethodological and CSCW-style field work that students do within their homes to inform in situ co-design projects (Dourish & Button, 1998). Observing organisms in the field through naturalistic observation is an invaluable practice for understanding an animal's behavior in its natural environment by recording its reactions to unmanipulated stimuli (Salkind, 2010). Ethnomethodologically-oriented inquiry and design inform one another. In the case of designing for non-human stakeholders, Animal-Computer Interaction researchers view co-design as a powerful method that gives animals more agency because of its integration of stakeholders into all phases of the design process (Sanders & Stappers, 2008; Hirskyj-Douglas et al., 2017). By establishing students' homes as valuable research and design sites, we counter the privileging of classrooms separated from homes as sites for learning; acknowledging students, and their pets, as equally valuable co-creators of knowledge using the physical places where they live, together.

Overview

We designed the camp to draw on the advantages of being at home, particularly the advantage of participants spending time with their pets while performing ethnomethodological activities and creating co-design projects. Placing science and engineering work in the context of the home situates participants' scientific inquiry and investigation within their pets' natural environment, amid all the normal stimuli and routines they encounter. We conjecture this learning environment design enables participants to draw upon funds of knowledge from their homes and relationships with their pets. We designed the first week of camp for participants to engage in scientific inquiry and investigation of their pets' senses, as well as to observe their pets' behaviors interacting with different stimuli. We designed the second week of camp for each participant to co-design a project with their pet to enrich some aspect of their pet's life. We distributed assignments and resources via Google Classroom and met weekday mornings as a group for one hour over Zoom. We designed a mix of asynchronous at-home activities, and synchronous activities to do as a group in our Zoom sessions.

Recruitment

We recruited middle and high school aged youths through a STEM mailing list of people who previously participated in a science or engineering summer camp. We used a flyer that described the virtual camp activities, including estimates of how participants would spend their time. The participation criteria were that participants were between the ages of 13–18, had at least one pet dog or cat at home, and had internet and computer access. 13 youths, 9 dogs, and 5 cats participated in our study with 11 youths completing the camp (see Figure 1).

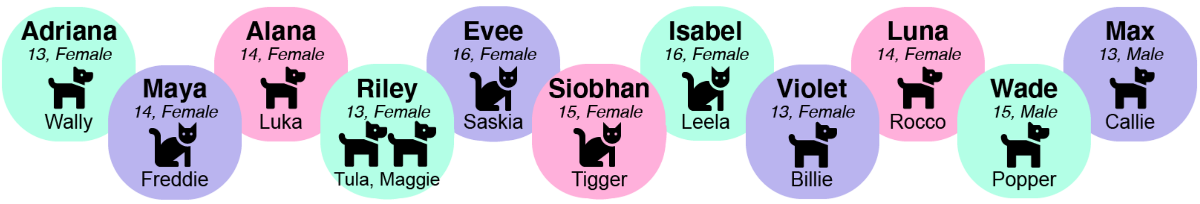

Figure 1. Participants' pseudonyms, ages, genders, and pet information.

Key asynchronous and synchronous activities

We shipped materials to participants to support their at-home activities and co-design projects. Each participant had a Pet Blog, which was a personalized Google Slides presentation where participants documented their at-home activities and co-design project. We orchestrated synchronous group share-outs over Zoom where participants reported their activity and project progress with the group. We also conducted group discussions (in full groups and smaller breakout groups) that helped participants generate ideas and questions for their later at-home activities. We used Google Docs and Slides, so participants could collaboratively comment on the document in real-time, post questions in the Zoom chat, or speak up verbally if they felt comfortable. For the first at-home activity, participants developed a mock social media profile for their pet and completed an ASPCA feline-ality or canine-ality assessment and reflected on their pet's personality type result (ASPCA 2007a; 2007b). Prior to this study, we developed two Snapchat lenses called DoggyVision and KittyVision (Kelly et al., 2020). These lenses simulate canine and feline visual differences: color perception, visual acuity, and brightness discrimination (Miller & Murphy, 1995). When users enable the lenses, they can see the effects in real-time on their phones' camera feeds and can capture photographs and videos of the scenes they are viewing—enabling participants to see their pets' home environments as they would. The day two activity was an at-home exploration with DoggyVision and KittyVision; participants viewed areas inside and outside of the house that their pets frequent using the lenses and took observational notes. On day three, participants designed an experiment using Doggy- or KittyVision to investigate a question they had about their pet's vision. On day four, participants observed their pet's reactions to different sound stimuli, and designed a wearable paper model of their pet's pinnae (outer ears) and made observations about their differences in their hearing and their pet's and wrote about sounds that stimulate or frighten their pets. Our day five activity (the last day of week one) was inspired by behavior tracking techniques from the animal sciences (Lehner, 1992). Participants observed their pets throughout the day and over the weekend and used their logs to make claims about their pet's emotional and mental states and the contributing environmental factors. Participants also used these techniques throughout week two for testing and evaluating their co-design projects with their pets. The week two activities guided participants through the process of creating co-design projects, including designing and building initial prototypes, and evaluating and iterating on their projects each day at home. At the beginning of week two (day six), each student wrote a proposal for a co-design project and developed a design persona ("pet-sona") to represent their pet as a co-design stakeholder (Hirskyj-Douglas et al., 2017). On days seven, eight, and nine (the penultimate day) participants provided daily project updates in class and in their Pet Blogs that included their project revisions, the methods they used to evaluate their project, and the results of their testing. Their results included successful aspects of their project and revision plans to address the unsuccessful aspects of their projects. On the penultimate day of camp, participants created a final video project presentation about their co-design projects. Participants presented their videos on the last day, while facilitators and campers asked questions.

Data collection and analysis

We saved participants' at-home Pet Blog work, in-class collaborative work, and recordings of all Zoom interactions. Additionally, we recorded exit-interviews with nine participants. We content logged and partially transcribed participants' exit-interviews, focusing on their experiences engaging in science and engineering at home. We performed a thematic analysis on the data, focusing on themes pertaining to participants' engagement in their at-home activities with their pets, and on how being at home shaped their practices and experiences regarding scientific experimentation and observation. As part of a larger analysis, we described in detail the links between science and engineering practices (NRC, 2012; NGSS Lead States, 2013), care, and empathy in participants' co-design work with pets. That work informed the analysis in this paper, where the emphasis is on how being situated in the home, with their pets, influenced the experience of doing science and engineering using the framework described in the Theoretical and Conceptual Background.

Findings and discussion

At-home activities as field work drawing upon funds of knowledge

The asynchronous camp activities promoted participants' enactment of ethnomethodological field work with their pets and in their homes. Situating this work in participants' homes with their pets enabled them to perform naturalistic observation, and to build on their funds of knowledge regarding their pets. One participant, Violet, reflected on the benefit of being able to participate at home with her dog from Texas (~950 miles distant from the facilitators' locations), saying, "this is [Billie's] environment and she knows it much better…her environment here is so much more different here than in Colorado." Violet's statement demonstrates the importance of place in this learning environment, particularly how participating somewhere other than their home would alter her and Billie's experiences of the camp.

Participants incorporated their and their pets' home environments and normal routines into their scientific work. For example, during the behavior tracking at-home assignment, participants logged their pets' behaviors and made arguments for what environmental stimuli in or outside the home were influencing these behaviors. Participants used this evidence, and drew on their funds of knowledge, to argue what their pets' emotional and mental states were. For example, Adriana's family had a visitor come over with a new puppy and she tracked Wally's interactions and behaviors around the puppy, writing observations such as, "If [the puppy] did something that Wally didn't like, he would growl at her. It was a low growl coming from the back of his throat." Based on Adriana's observations of Wally's growling, and engaging in behaviors such as "stalking her" and "try[ing] to stand up taller and appear bigger," she argued Wally was feeling territorial and therefore trying to assert his dominance over the puppy. In addition, when Adriana was evaluating Wally's interaction with her design project (a comfortable napping crate for Wally), she noted similar growling behavior. Adriana knew to associate growling with territorial behavior, therefore, Adriana noted this as a sign that Wally liked the napping crate. She wrote, "he was protective of the crate, and was thinking of it as his." The ability to observe Wally at home enabled her to see these territorial behaviors; had she and Wally participated in a different location Wally would not display the same ownership and comfort of the space.

In addition to the importance of *place*, the behavior tracking assignment displayed the importance of *relationships*; particularly, the value of participants' intimate knowledge of their pets. Adriana had knowledge of

Wally's sleeping preferences, saying "[Wally] loves resting in tight spaces...When he's napping, he'll often do it behind the dinner table, or up against the wall or couch." This knowledge of Wally's sleeping preferences is what led Adriana to choose to design a new, comfortable sleeping space for him for her project. This use of prior knowledge was also prevalent in one of Riley's behavior logs. Riley noted, unlike other dogs, Tula does not wag her tail when she is excited. She wrote, "[Tula] never really straightens her tail so this is just in its normal position...she is enjoying it too much to think about wagging it." Riley's assessment of Tula's mood required intimate knowledge of her behaviors. Whereas an outside researcher or other camper may have perceived Tula's lack of tail-wagging as a sign of discontent, Riley utilized her prior knowledge and relationship with Tula to explain why the opposite was true. To demonstrate the importance of participants' funds of knowledge, we offer a contrasting example; one participant, Maya, adopted her kitten Freddie only an hour before the camp started. Therefore, she lacked the prior knowledge about her pet that develops over time in a relationship. Maya could only perform on-the-spot naturalistic observation, which was also difficult because Freddie was nervous about his new home and tended to hide when she wanted to interact. In reference to this problem, Isabel said "[The feline-ality test] would be difficult for new animals because these animals may not have begun to form unique behaviors and figured out how they handle the world…[Leela] has become a little lazier and less social as she's aged."

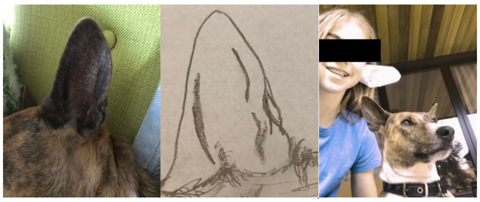

Figure 2. Alana's photograph of Luka's ear, a sketch, and her wearing the paper model she designed.

Situating the camp at home was beneficial towards participants' understanding how their pets' senses of sight and sound operated in their natural environments. Participants' use of DoggyVision and KittyVision in and near their homes allowed them to view their pets' natural environments with their simulated color perception firsthand. During Alana's initial explorations with DoggyVision in her home, she took a photograph of a view outside a window that her dog Luka often stares out. In her photo caption, Alana wrote, "this is the view out of a window that [Luka] likes to sit by. The colors are a lot less brilliant and the red flowers across the street blend in with the grass." Not only was Alana building a model of dogs' color perception, she was also viewing the world from her dog's day-to-day perspective—something impossible to do in a school classroom or at a centralized camp location. During the hearing activity, participants observed their pets' reactions to different sound sources and stimuli in and around their homes, as well as recalling prior knowledge of their pets. Alana wrote, "Whenever someone knocks on the door, [Luka's] head shoots up and he becomes very alert." Some participants made note of sounds related to feeding time, Isabel wrote, "We know that [Leela] knows the sound of her food cans opening, as she always runs when she hears it. We also see her react to my dad calling them to dinner." These observations required no manipulation of their pets' environments, and heavily relied on their prior knowledge. Participants' ability to work on the hearing assignment at home also enabled them to record up-close observations of their pets' ears and create detailed sketches of their appearance. This allowed them to design their paper models to more closely resemble the shape of their pets' unique ears, as opposed to a generic dog or cat model (see Figure 2).

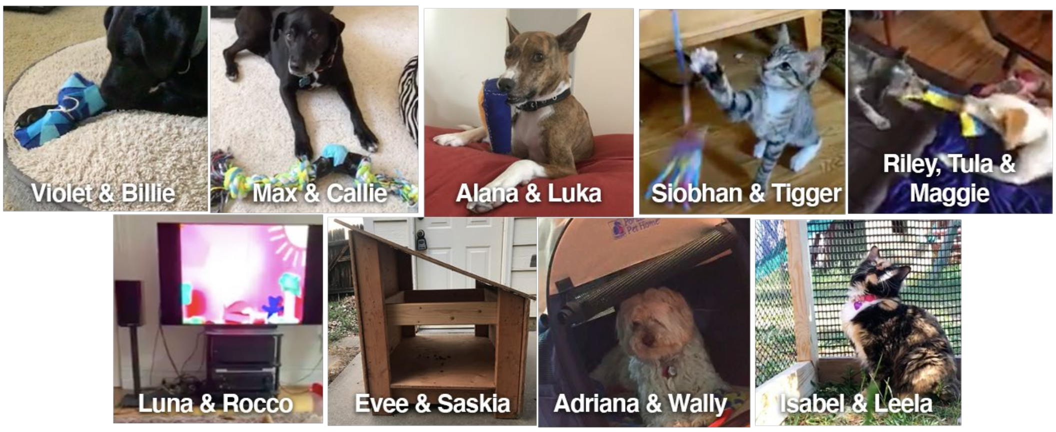

Figure 3. Participants' final co-design projects in use by their pets.

The ability for participants to engage in their experimental and observational activities with their pets at home enabled them to enact ethnomethodological practices and understand their pets' behaviors and senses in their natural environments (Dourish & Button, 1998). In addition, working from home allowed them to build on their funds of knowledge they have from their relationships and cohabitation with their pets. These practices helped participants produce more authentic data about their pets for them to develop hypotheses and to use in their co-design projects. Because each student's co-design project focused on improving their pet's quality of life, students' funds of knowledge helped provide empathetic motives for their design interventions. Students' co-design projects fell into two major categories: 1) new toys that were tailored to their pets' specific wants and needs and 2) spaces or environments that would make their pets feel comfortable and safe (see Figure 3).

In situ co-designing with pets

The ability for participants to work on their co-design projects from home allowed them to create projects that integrated seamlessly into their homes, and enabled participants to engage their pets in all stages of the design process, whereas participating in a classroom or camp location outside of their homes would create disjoint stages of iteration and evaluation. All phases of designing were situated in the context of theirs and their pets' natural lives: understanding stakeholder requirements (which we highlighted in the last section through examples of participants' at-home field work and observations), prototyping, evaluating, and revising.

As an initial stage of their co-design projects, participants developed design personas ("pet-sonas") for their co-design projects. Luna wanted to design a TV show for Rocco and wrote down her observations of how Rocco typically interacts with the TV, "Rocco loves to watch the tv when my family is sitting near it watching a show. He enjoys the sounds and visuals on the tv screen...when there is a loud or interesting sound his ears will perk up and he may run over to the screen." Luna's description captures both how Rocco interacts with the television, and also how his interest in the television is tied to spending time with the rest of the family. Isabel wanted to build an extension to her cat's current outdoor enclosure for her project, so she wrote about how Leela typically interacts with the current enclosure, "Leela mainly spends her time on the ground, eating grass, but she also enjoys the vertical shelves, which gives her a vantage point...she often claws at the fencing and clearly wants to be able to move around freely" (see Figure 4).

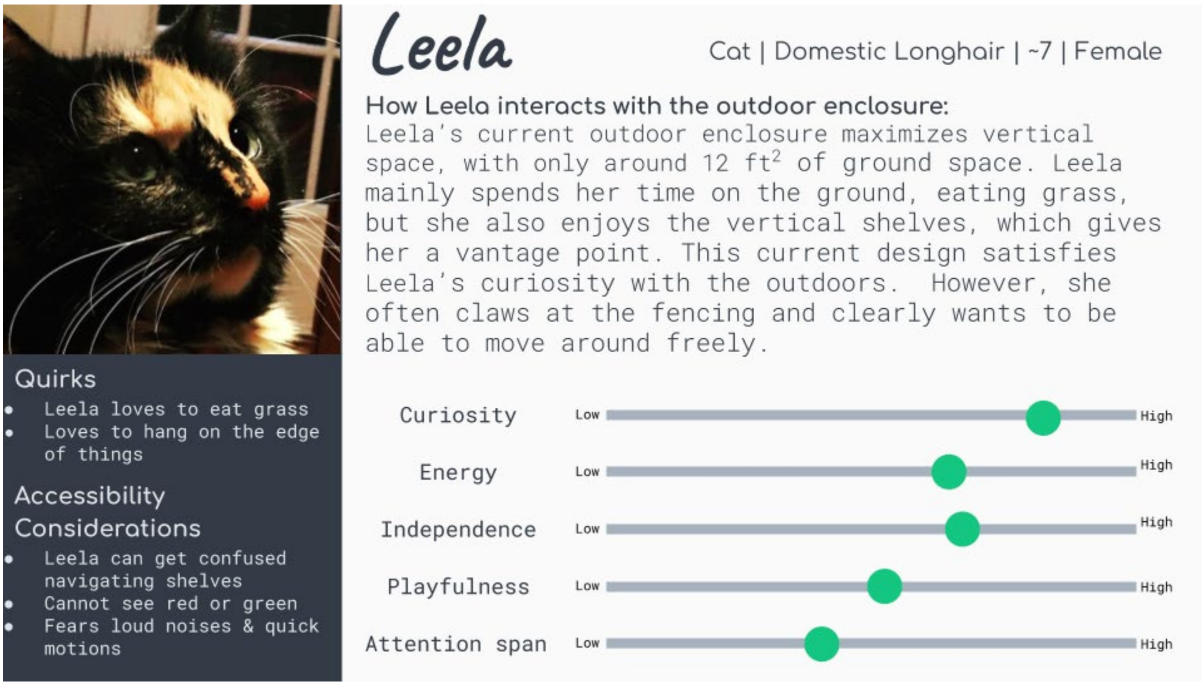

Figure 4. Isabel created this "cat-sona" to represent her cat Leela.

Conducting experiments and testing their projects at home with DoggyVision and KittyVision allowed participants to determine what colors were visually accessible for their pets in their natural environments, and to eventually evaluate what their prototypes looked like in their own homes. Figure 5 shows Violet's experiment she conducted with Billie to investigate whether she had a particular color preference in her toys. Being at home gave

Violet access to Billie's toys, as well as the ability to experiment in situ with Billie in an unmanipulated environment familiar to both dog and human. In her tests, Violet played with Billie in her normal habitat (the living room), and Violet collected DoggyVision photos to see how Billie's toys looked on their carpet. Based on her tests, Violet ascertained that bright blue was the most engaging to Billie, which led her to design a toy prototype that included varying shades of blue. Similarly, Riley used DoggyVision to observe how her toy prototype looked on different surfaces (grass, concrete, wood floor) to test if the colors would be visually accessible to her dogs. She wanted to compare the appearance of the new prototype against one of her dogs' old ratty toys to evaluate whether or not there was a visual improvement. Riley collected side-by-side photographic evidence of the old toy and new toy in three different locations: the backyard, the back deck, and a room in the house (see Figure 6).

Figure 5. Violet's documentation of her color preference test with Billie

Figure 6. Riley's side-by-side DoggyVision photos of her dogs' old toy and her new toy prototype.

Situating the co-design projects at home required participants to develop a sense of their pets' schedules and behaviors throughout the day. Many participants had to adapt their testing methods depending on the time of day. For example, Siobhan tried to keep her testing times consistent because Tigger was more active in the evenings and "his energy level also changed how he reacted to the toy." Similarly, Evee was worried that testing her prototype at night would cause her to have to force Saskia to interact with it because of the rushed timeline. To address this, she said "I made my changes and set it up in the late morning so that [Saskia] would have all day to explore it and get used to it if she wanted to." Sometimes, the pets were in control of when tests took place. One time, Riley was in a Zoom session and Maggie wanted to play with her and the toy prototype, "While I was on a zoom meeting she was chewing on the toy for a relatively long time. I think she liked the crinkling of the plastic and the smell of the treats and the sound of the rattle when it rolled." This ability for participants to adapt to their pets' needs and routines allowed for impromptu discovery and is a valuable skill for performing in-situ co-design work. In addition, participants who designed toys for their project were able to engage their pets in frequent "play tests" inside and outside of their homes, which situated the process of design and evaluation in a mutually enjoyable activity that established relationships and location as a valuable part of their design processes.

Another advantage of participants working from home was their ability to use at-home resources, and household materials relevant to their personal hobbies and interests. Although we supplied each participant with a box of supplies, all participants used at least one item from their own home for their project. In addition, participants explicitly designed their projects to be a part of the home. Isabel's co-design project was to extend her cat's outdoor enclosure which was attached to the house. Isabel and her cat, Leela, live in a small mountain community where outdoor cats can fall victim to larger predators. Isabel wrote, "[Leela] really likes going outside but it's not really safe for her to do here." Based on her prior knowledge and observations of her cat, she identified Leela wanted more space in her enclosure, saying, "she often claws at the fencing and clearly wants to move around more freely." Isabel's project involved several large pieces of plywood and power tools, which would have been cumbersome or even impossible to transport back and forth between home and school. Because participants worked on the entirety of their projects at home, they did not need to transport their project materials. In addition, participants could always test their projects in situ because of the constant access to their pets. For example, when Isabel finished sizing her initial extension, she wanted to make sure it accommodated Leela before the next step of putting it all together, "In order to test the revisions to my prototype, I laid out the materials for the extension outside...I will let Leela stand in the structure tomorrow, to ensure that she can fit comfortably" (see Figure 7). Prior to constructing the extension, Isabel built a prototype model using craft materials at home (see Figure 7), saying the experience "helped me realize how to use things in my house." To bring her prototype into fruition, Isabel's father supported her interest and drove her to the hardware store several times to buy materials, which was about an hour and a half round trip drive. Isabel had experience with woodworking at home and from a high school class, saying she "did as much of [the project] as possible on my own," but that her father taught her to use their saw and helped her drill, so she would not damage the house. Isabel's project shows how personal interests, family support, location, and funds of knowledge can connect to an at home co-design project with a pet. Isabel was not the only person whose project connected to a hobby; Riley described herself as being good at sewing and applied this skill to her project creation, "I will sew up my toy with a sewing machine but hand stitch on the smaller sections. I am a good sewer and like to sew clothing and other things in my free time." Riley's statement demonstrates her integration of a personal interest (sewing) into her design project.

Figure 7. Isabel's model prototypes (A and B), the materials Isabel laid out to test the enclosure size (C), and Leela enjoying the final enclosure (D).

Situating participants' co-design projects at home allowed for a cohesive process of design iteration and evaluation and enabled participants to perform authentic design interventions. Participants created projects specifically designed for their homes and pets, and even integrated their personal hobbies and interests to their projects. Participants developed adaptable testing procedures that worked around their pets' schedules and allowed for spontaneous discovery.

Conclusion

In contrast to Ann Brown's (1992) groundbreaking design experiments in the early days of the learning sciences which were radical in situating what used to be called "educational psychology" in the "blooming, buzzing confusion" of classrooms, we explored what could be gained by working in the blooming, buzzing context of learners' homes during a pandemic that made gathering in in-person groups for summer camp impossible. Facilitating a remote STEM summer camp enabled us to situate participants' scientific, design, and engineering activities within their own homes, building on their relationships with their pets and their funds of knowledge while participating in structured learning activities with a distributed group. Participants conducted activities with their pets at home; allowing them to engage in ethnomethodological fieldwork practices such as naturalistic observation and in situ design and draw on prior knowledge they have about their pets. The ability for participants to work in their free time, allowed them to test with their pets at optimal times, which involved learning to adapt to their pets' behaviors and schedules. This flexibility in designing in situ allowed for more authentic data for their co-design project iterations. Even though we applied an asynchronous, distributed learning model out of necessity, we believe this type of learning environment should always include some level of asynchronous at-home work due to the advantages we have highlighted. One downside of remote participation several participants mentioned was the lack of connection with other campers. To address this, future iterations could seek to enhance social interaction and community-building among campers, through additional in-person or online activities that foster interpersonal interaction and collaboration, while still situating the core experimental and observational work within participants' homes. Our experience points to a lesson for designing the location of learning experiences: changing the focus to what ethnomethodological fieldwork and design work makes sense to do remotely as asynchronous "homework" (in this case at home where learners lived with their pets), and what social and interactional work makes sense to do synchronously, with various inscriptional tools used to support either remote or face-to-face discussion.

Choose Your Evidence: Scientific Thinking Where It May Most Count

Deanna Kuhn, Columbia University, dk100@columbia.edu
Anahid S. Modrek, Thomas Jefferson University, anahid.modrek@jefferson.edu

Abstract: Schooling traditionally affords students more experience in learning and practicing procedures than in identifying what a situation calls for. When asked to choose appropriate numerical data to support their causal claims, college students perform surprisingly poorly. In one case we describe, almost all chose limited, inconclusive data as sufficient evidence, despite having available the more comprehensive data needed to support their claim, and despite their established competence to employ such data for this purpose. Our objective in highlighting this weakness is to make a case that choosing one's evidence warrants the status of an important metacognitive intellectual skill and educational objective, one central to but that extends well beyond the domains of scientific and mathematical reasoning and hence warrants greater attention both in and beyond the science curriculum. People may choose evidence to justify their assertions in an ill-considered way, with potential adverse effects in both private and public communication.

Keywords: judgment, reasoning, argument, evidence, discourse

Introduction

We live not only in a time of information proliferation (Hills, 2018) but a time that allows, even encourages us to "Choose your news," and from this news, to choose your facts. The latter implies our choosing the evidence to support those facts, should we need to do so. The following discussion illustrates some common possibilities in choosing evidence to substantiate a claim.

AL: The US tax system is unfair. It's rich people who are most likely to cheat on their taxes.
BEN: I know. Some of us should write a letter to the editor making people aware of this.
AL: Should we include anything to prove our point?
CLAY: I've known a lot of well-off people who cheat. We just need to point them out.
DON: But there are others who don't.
AL: But how many?
BEN: Maybe we could show there are more that do than don't. That should do it.
CLAY: I think it would be more convincing to focus on the cheaters and show they are most often rich.
AL: But there are lots of poor people. At least some of them must cheat.
BEN: Right. And there are a lot of rich people who don't cheat. So I think that kind of disproves our point. It's not clear-cut. Maybe we'd better forget this.
DON: But wait. There are probably a lot more rich cheaters and poor honest taxpayers, than there are poor cheaters and rich honest ones. So that would prove our point.
ED: Hold on, I've got a simpler idea. Why don't we just compare the percentage of rich people who cheat to the percentage of poor people who cheat?

Evidence in the form of Ed's final suggestion is appealingly simple. The form is also one seen very frequently in a wide variety of print or other media. Yet each of the other forms portrayed above are not uncommon and are based on responses we observed in recent work (Kuhn & Lerman, 2021). We think they are important because they highlight a form of everyday scientific thinking having serious consequences. Moreover, it is a form that science educators arguably have neglected to students' disadvantage.

Our objective here is to make a case that choosing one's evidence warrants the status of an important metacognitive intellectual skill and educational objective of broad relevance, one that is central to but extends well beyond domains of scientific and mathematical reasoning. Our focus in making this case is the common context in which people have a free hand in choosing what serves as sufficient evidence to support their own claims or to accept others' claims – hence a context that invokes disposition (rather than only procedural or strategic competence) and serves to identify the epistemological standards an individual subscribes to (Greene, Sandoval, & Braten, 2016; Mills, 2013; Metz, Weisberg & Weisberg, 2018; Moshman, 2015).

A rapidly expanding body of work now exists on argumentation and most recently in particular the role of evidence in argumentation – studies that highlight the complexities of different forms of evidence and the distinct roles they play in relation to a claim (Duncan, Chinn, & Barzilai, 2018; Hemberger et al., 2017; Iordanou

& Constantinou, 2015; Jiménez-Aleixandre & Puig, 2012; Macagno, 2016; Macagno & Walton, 2018; McNeill & Berland, 2017; Miralda-Banda, Garcia-Mila, & Felton, 2019; Monteira & Jiménez-Aleixandre, 2016; Sampson & Clark, 2008; Shi, 2019). These studies point to overall weakness in key skills of recognizing the critical role of and effectively using evidence to both support and weaken claims, in both individual written and verbal argument and in dialogic argumentation with others. Such skills do show improvement, however, with engagement and practice (Kuhn & Crowell, 2011; Hemberger et al., 2017; Iordanou, 2010; Iordanou & Constantinou, 2015; Rapanta, 2019; Reznitskaya & Wilkinson, 2017; Ryu & Sandoval, 2012; Shi, 2019). In general, progress in dialogic argument precedes that in individual argument (Kuhn, 2019; Kuhn & Moore, 2015; Mayweg-Paus & Macagno, 2016; Shi, 2019). Initially, the essays of novices consist largely of supporting arguments for a favored position. Later to appear are attention to and arguments seeking to weaken the opposing position. Only more gradually do essays begin to include mention of possible strengths of the opposing position or weaknesses of the favored position, and later still the "However" statements that serve to connect and weigh opposing arguments. Also gradually increasing is the use of evidence to weaken as well as support claims (Hemberger et al., 2017; Shi, 2019).

In the present discussion, our focus shifts from the one common to the body of research just cited – individuals' competence in making effective use of evidence in their arguments and argumentation – to a focus on their disposition to do so. Disposition becomes critical when people have a largely free hand in deciding whether and how to bring to bear evidence to support a claim they believe is correct, a situation we have suggested is a common one in natural conversational contexts. Yet it has been the subject of much less investigation, except perhaps less directly in research on epistemological understanding (Greene et al., 2016; Moshman, 2015), in which people are queried regarding how they know what to accept as true. Another related contemporary line of research examines how people react to "fake news" and the attributes of the source and of the receiver of such news in affecting whether such news will be accepted and whether it will be relayed to others (Barzilai, Tzadok, & Eshet-Alkalai, 2015; Barzilai & Zohar, 2012; De Keersmaecker, Dunning, Pennycook, et al., 2019; Lazer, Baum et al., 2018; Pennycook & Rand, 2018). In addition to the factors of source credibility and cognitive and personality characteristics of the receiver, however, is the form of the evidence one selects as bearing on the assertion and one's judgment regarding its sufficiency and strength. It is this epistemological dimension of understanding of evidence, and its significance in science education, that is our concern here.

One of us has written at length about mature epistemological understanding as a developmental achievement that many individuals do not complete (Kuhn, 2005, 2009, 2020). Its achievement is foundational to the disposition, as distinguished from competence, to think critically or to engage in what has been coined epistemic vigilance (Sperber, Clement et al., 2010; Settlage & Southerland, 2019). Early conceptions of knowledge as reflecting an objective reality evolve toward a more correct one of knowledge as constructed by human minds (Iordanou, 2017). Initially, however, this construction is understood as yielding only a multiplicity of subjective opinions that knowers are free to adopt at will in the form of personal possessions. This multiplist level of understanding offers a way of making sense of adolescents' discovery of the existence of multiple, often seemingly reasonable yet diverging claims. Only at a next level do subjective and objective dimensions become coordinated in an understanding of knowledge as judgment (rather than immutable fact or unconstrained opinion), based on evaluation in a framework of alternatives and evidence (rather than immutable fact or unconstrained opinion). The marshalling of evidence as a means of supporting or challenging claims thus assumes its key role, as an essential tool in distinguishing among conflicting claims.

An examination of evidence choice among college students

In the study we draw on here, 43 college students enrolled in the initial weeks of an introductory statistics course at a small liberal arts college in the Northeast US. Their ages were mostly in the early twenties, about two thirds female. Three quarters identified as White, with the remainder African American, Latino/a, and Asian. The college is selective in its admission and serves a largely homogeneous, upper-middle to upper class population whose families can afford to pay the high fees the institution charges. They served not as a convenience sample but as a sample of a population that are widely expected to hold standards higher than those of an unselected population with respect to their exercise of care in drawing unsupported inferences. Critical thinking, after all, is regarded as among the most highly valued achievements of a college-level education.

The main problem introduced in writing was this: A National Health Data Bank have identified children's obesity (excess weight) as a concern and want to determine the cause. They have collected information from a broad, representative sample of 200 American four-year-olds, these are the numbers they came up with. Each card shows the children they identified who fall into the category shown on that card. The Data Bank researchers now need someone to analyze the results and to write a summary report of what these findings show about the causes of young children's being overweight.

Students were presented a set of 19 cards ordered randomly, each containing a different kind of information pertaining to this sample of 200 four-year-olds. They were told they could examine and organize the cards in any ways they wished as preparation for writing their reports, and the cards remained available to them while they wrote their reports. The cards fell into two categories, those that contained numerical data and those that did not.

Of the 19 cards, 12 introduced numerical data – just a single number, identifying the number of children who did/didn't possess a binary attribute and who were/weren't overweight, e.g., "This card lists cases of CHILDREN WHO DO NO EXERCISE and ARE NOT OVERWEIGHT. NUMBER OF CASES: 30 [of 200 total children observed]." (See Figure 1.) The information each card contained is summarized in Table 1 (see below), one number per card. As reflected there, the information suggests a strong association between exercise and weight, a moderate association between diet and weight, and a negligible association between parent weight and child weight at age 4. (No information was available regarding cross-classification of individuals in multiple categories, of a sort that would allow assessment of additive or interactive effects of the three identified variables on the outcome variable.)

This card lists cases of CHILDREN WHO **DO NO EXERCISE** and ARE **NOT OVERWEIGHT**.

NUMBER OF CASES: **30** [of 200 total children observed]

Names of 30 cases: XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX XX

[names deleted for confidentiality]

Figure 1. Sample evidence card.

Table 1: Numerical values appearing on 12 individual cards (one value per card)

	Overweight	Not Overweight
Exercise	20	90
No exercise	60	30
	Overweight	Not Overweight
Regular diet	40	80
High-calorie diet	40	40
	Overweight	Not Overweight
Parent average	20	90
Parent overweight	60	30

Included in the 19 cards were seven that contained no numerical information, included to assess whether statements containing no or incomplete evidence would be regarded as evidence. Four were simply assertions made by a possibly authoritative source (e.g., "Dr. B. Marcy of Beacon clinic claims that parents' body type affects children's likelihood of being overweight"). The remaining three were assertions of prevalence of an outcome variable level (e.g.," Dr. F. Prentice sees a large number of children in his practice and reports that a majority of them are overweight or of a potentially causal variable level (e.g., "Dr. K. Lester reports a large number of children in her practice do not get enough exercise").

Most students organized the numerical cards and began by recording the information from them on a provided sheet, using various formats (typically simply a list, but occasionally in a branching chart form or as a histogram). In their reports most then showed numerical calculations followed by inferences, although some showed only calculations and others only inferences. Patterns of performance were categorized based on how many of the four cells in a cross-tabulation table (as shown in Table 1) a student utilized. A variety of patterns appear, but almost none reflect the correct comparison of two proportions. An illustration of the one that did appears in the final row of Table 2 (see below), striking in its simplicity. Descriptions of categories and their frequencies appear in Table 2 by category, with illustrations for each. As seen there, examples for each of the categories show that students in every category displayed little hesitation in advancing causal claims.

The categorization system in Table 2 is an objective one, based only on how many of the four cells were utilized. Categories are listed in order of number of cells utilized. Each participant is counted only once, based on highest performance level exhibited. (Performance patterns differed little when categorizing by modal strategies, which were of course slightly lower.) The majority of reports addressed two or more of the three factors. Among those who addressed at least two factors, most – 26 of 35, or 74% - used the same strategy in analyzing two or more of the three variables for which data were available.

Table 2: Patterns of performance on causal analysis problem (n=43)

Pattern	n	Examples
No data referenced but one or more inferences made	7	Based on the cards, obesity seems to be based on diet, exercise, & overweight parents.
No data referenced and no inference made	2	From this data we'd be able to crunch the numbers and compare percentages because of the sample size being consistent across the board.
One-cell referenced with causal inference	6	Because exercising and not-overeating has highest total – 90/200 – it is an indication that children who exercise more are at less risk of being overweight.
One-cell referenced without inference	4	This card shows the greatest number of cases who exercise and are not overweight, indicating it might be a key factor. However, no direct cause can be determined since there are multiple confounding variables that affect accuracy such as family income.
Two adjacent cells referenced with causal inference	7	Overweight children outnumbered not-overweight children in the do-not-exercise category. This tells me that the biggest factor in becoming overweight is not exercising enough.
Two adjacent cells referenced with noncausal inference	5	I found that a parent's weight does not play a part in a child's weight because there was a larger outcome of non-overweight children with overweight parents than overweight children with overweight parents.
Two non-adjacent (diagonal) cells referenced without inference	3	Some say children who exercise are overweight, some say they are not. They contradict one another. This shows there is no clear-cut answer to the question of factors that cause obesity.
Two non-adjacent (diagonal) cells referenced with inference	3	Out of 200 children, 75 had a parent who was not overweight and those children were also not overweight. On the other hand, 35 children out of 200 were overweight and had an overweight parent. So parent weight matters.
Four-cell reference with causal inference	5	Exercise matters. There are a high number of kids who exercise and are not overweight. Another high number who don't exercise are overweight. The other 2 cards have little number of cases.
Four-cell proportional reference with causal inference	1	The data show children who eat a low-calorie diet are less likely to become overweight – 80 aren't & 40 are. High-calorie shows an equal number on each side.

One might attribute such causal judgment weaknesses to limitations in skill in proportional reasoning. Long documented are the difficulties students exhibit in mastering proportional reasoning, even among those who have performed well in mathematics to this point (Tourniaire & Pulos, 1985; VanDooren, Vamvakoussi, & Verschaffel, 2018). (A weakness in employing all relevant frequencies has been referred to as neglect of base rates in the adult cognition literature; Kahneman, Slovic, & Tversky, 1982.) A second problem administered either before or after the main problem, however, made this interpretation less likely: "Susie and Sally are setting up lemonade stands. Susie is mixing 6 cans of lemon juice and 3 cans of water in her pitcher. Sally is mixing 4 cans of lemon juice and 1 can of water in hers. Whose lemonade will taste more lemon-y and why?" All but one student solved this problem correctly and provided appropriate reasoning, despite the problem structure encouraging an erroneous conclusion. A correct response incorporated all four values into the calculation and related them in terms of a ratio (2:1 vs. 4:1) or proportion (66% vs. 80%). Only two students failed to do so, comparing only the absolute amounts of water in each pitcher ("Sally's because she's using less water") in one case or in the other using a proportional strategy but incorrectly. Thus, an inability to reason proportionally does not explain students' challenges in the main problem. Nor did administration of the lemonade problem before rather than after the main problem serve as a prompt to improve performance.

What might students (and educators) be missing?

Wherein then lies the problem? At one level such data might be taken as a further cry of alarm regarding poor mathematics achievement of American students, up to and including students of college level. Mathematical proficiency at the level we examined extends well beyond mathematics itself. It is fundamental to science education (Hilton & Hilton, 2016), as well as foundational for numerous other fields within business, economics, engineering and beyond. The findings are consistent with lines of research in developmental psychology that have demonstrated early competence yet later weaknesses that become apparent at an older age. Proportional reasoning is one such case. Denison and Xu (2019) describe infants' abilities to make at least implicit judgments of proportion, and they offer the recommendation that proportion can be introduced profitably much earlier in the school curriculum, thereby weakening what has been referred to as the whole number bias that is reinforced by early mathematics instruction (Siegler, Thompson, & Schneider, 2011).

The evidence described here certainly supports the recommendation of earlier emphasis on proportion in the mathematics as well as science curriculum. At the same time, it suggests that more or better instruction on proportion is not the whole answer. Students were almost all able to execute a proportional reasoning strategy in a simple numerical context. Executing the strategy, however, did not in turn serve as a prompt to apply the strategy in the main problem, which offered three distinct opportunities to do so (for each of the three proposed factors possibly linked to outcome). Those who encountered and successfully solved the lemonade problem immediately before encountering the main problem did no better on the main problem than did those who encountered it only after the main problem. This finding highlights the broad and ubiquitous dilemma in educational psychology of failure to achieve transfer, and more specifically in the mathematical context it points to the need to maintain continuing interplay and coordination between procedural and conceptual knowledge (Rittle-Johnson, 2017).

Both elementary causal and proportional reasoning, in any case, should have been within the competence of college students. Children in the first decade of life commonly infer causal relations based simply on co-occurrence, but by late adolescence most have learned the control-of-variables strategy of holding other factors constant before inferring a causal relation between antecedent and outcome, even though they continue to struggle with multivariable causality involving multiple contributors to an outcome (Kuhn, 2012; Teig, Scherer, & Kjaernsli, 2020).

A further factor in participants' favor in the present task is the fact that the context in which students were asked to apply these skills was a favorable one, and context means a great deal in affecting the classroom behaviors students display (Jiménez-Aleixandre., Rodriguez, & Duschl, 2000; Kuhn, 2005; Settlage, & Southerland, 2019). The context was a statistics class in which students would have been aware that their mathematical skills were to be made use of.

If the context was supportive and skill in proportional and causal reasoning was not at stake, what then prevented college students from applying their skills in the main problem, where it would have been not just highly useful but essential? Why did they not recognize the need to do so? The answer to this question reaches beyond the realms of mathematics or science. We suggest it lies in an atypical degree of freedom the main task offers students in organizing a response to it. Research studies frequently present data to participants and ask them to analyze it and draw implications from it. What was uncommon in this case is that the student had to choose what data to call on. As noted earlier, the problem thus becomes one of epistemological standards: What constitutes relevant evidence and what constitutes sufficient evidence? This challenge is not only infrequent in research tasks but infrequent in most students' educational experience as well, in science or math classes as well as elsewhere. Especially in mathematics problems, students early on become aware that the numbers that appear in the problem are the ones to use, and the task is simply to figure out how to do so.

Students were able to choose appropriate evidence at least in the limited sense of categorizing the data points according to the potential causal variable being considered, but this achievement required little more than category-name matching. On the positive side, they did, however, largely ignore the cards that lacked numbers and contained only single-case assertions. Those who mentioned them did so only to comment that the assertion had been supported or contradicted by their data analysis. This contrasts with performance of middle-school students to whom we have given this problem, who frequently included reference to one or more of the non-numerical cards as support for one of their conclusions.

The performance college students displayed here, in selecting from and implementing procedural knowledge in mathematics to address a real-world problem, we believe bears on long-standing debates in science and mathematics education. Computational procedures like long division that students traditionally have learned to perform by hand are today increasingly seen as pointless by students, if not by their teachers as well. What should take their place? Should basic statistics replace the algebra and trigonometry for the great many students who find studying them tortuous as well as seemingly useless? These questions lack easy answers. Yet education science is now advanced enough to make clear that students need to find purpose in what they seek to learn or they are unlikely to succeed. Thus, coming to appreciate how mathematics addresses real-world problems is arguably an essential dimension of modern mathematics education.

A further objective arguably is the metacognitive development and practice that will allow students to recognize and apply effectively the strategic knowledge they do have in the wide range of contexts where it will serve a purpose. The college students described here showed little caution in making claims, almost all confirming causal (rather than non-causal) relations (and this applies across all the strategy categories identified). Only one expressed concern with potential interactions among the three variables, despite their likelihood, this student noting that the cards didn't provide cross-classification information that would be necessary to assess this possibility. Nor did many show understanding of the critical distinction between correlation and causality, even though a few used such language ("I've determined exercise and diet cause obesity…parent weight is just a correlation"), with only one correctly noting that all the provided data were only correlational, limiting conclusions. Finally, almost all took the three variables for which data were available to be the total set of potential causal contributors. The three who noted the potential contribution of additional variables (named or not) most often did so to explain cases that did not conform to the (diagonal) pattern of association between antecedent and outcome variable.

Our own further objective here has been to illustrate the implications of such data beyond achievement in mathematics to the broad realm of everyday reasoning and discourse. The students who participated in the work described here exhibited the epistemological failing of subscribing to very weak evidence standards for making causal inferences, leading to concern about their susceptibility to accepting without scrutiny similar unsubstantiated claims they encounter in both their academic work and outside of it. The sorts of incomplete data that these students chose as good evidence for a causal connection are ubiquitous in electronic and print media. The consequences for both personal and public discourse have of late become painfully evident.

What if anything can we point to as at fault in the pre-college educational experience of such students? The explanation we would propose has to do with weaknesses in the curriculum but of a particular sort. Students are not afforded the practice in autonomy that they would benefit from – autonomy affording them rich experience in deciding what to do, what information to consider, what additional information to look for, when multiple possibilities are available – in short, in taking charge of their own thinking and learning, in school as well as non-school contexts. Learning is now widely recognized by educators as more likely to be successful when learners experience what has been termed epistemic agency in conducting their own purposeful learning, learning directed toward sense-making (DiSessa, 2000; Elmore, 2018a,b; Rudolph, 2014; Scardamalia & Bereiter, 2015; Sikorski & Hammer, 2017), more than acquisition and retention of new information or procedures. Employers similarly now commonly express a wish for employees who can quickly make sense of new situations, determining what they need to know, learn it, and implement it appropriately as needed.

In short, cognitive self-regulation should be nurtured from an early age and is predictive of positive educational outcomes (Modrek & Kuhn, 2017; Modrek et al., 2019). Its importance becomes critical in scientific and indeed all higher-order thinking, where practice is key to its development, both with peers and in apprenticeship with more skilled others (Arvidsson & Kuhn, 2021; Kuhn, 2018, 2019; Mehan & Cazden, 2015; Mercer & Littleton, 2007; Papathomas & Kuhn, 2017; Rapanta, 2019; Reznitskaya & Wilkinson, 2017). However, individual cognitive weaknesses, of the sort highlighted by the data presented here, should not be overlooked by an exclusive focus on the study of thinking in social contexts (Kuhn & Modrek, 2018). In current work with middle-schoolers we are investigating ways to develop and strengthen the individual epistemological awareness and self-regulation that will improve performance on the kind of task discussed here.

We began this manuscript by suggesting the worrisome implications of adults in today's world becoming comfortable with choosing their evidence as a function only of their goals and needs (Mercier & Sperber, 2011), leaving their claims free to take whatever direction they wish. Potential remedies, however, lead us squarely back to education. Certainly, by college age, students need to be able to know what they need to know as they reason and learn. And they should be able to inhibit themselves and challenge others in advocating claims that lack the necessary evidence (Mills, 2013). In short, students must be equipped with needed knowledge and skills while prepared to assume responsibility and control over their own learning and knowing (Elmore, 2018a,b; Scardamalia & Bereiter, 2015). The eventual downside of their not doing so is arguably a contributing factor to the declining standards apparent in contemporary public and private discourse. This is certainly the case on topics that require attention to empirical evidence, as do all topics in the domain of science, and science educators are arguably in the best position to address them in educating the next generation.

Abstract: This article discusses how Minecraft: Education Edition (MEE) can be used as a teaching aid in social studies and as a digital learning resource to facilitate the development of generic and subject-specific competencies. The study reports from an intervention in a teacher education program where student teachers recreated historical environments of the industrial revolution along the river Aker in Norway. The rebuilding of the industrial revolution in MEE was conducted through three phases: introduction, reconstruction and transformation. These phases are illustrated with empirical data. This approach to teaching student's history emphasizes active learning by making it more engaging.

Introduction

Engagement and motivation are often cited as justifications for using computer games in teaching (Callaghan, 2016). Research on the use of digital games shows that they provide opportunities for engagement and activity among students, but the learning outcomes have also been questioned (Kluge, 2016), and computer games as a digital learning resource are met with skepticism from both teachers and parents (Dikkers, 2015; Sigurdardottir, 2016). Minecraft appeals to children because the threshold for participation is low, while the opportunities for creativity and role-playing are many, and the game allows children to build and collaborate with others (Mørch, Mifsud & Eie, 2019). Our aim is to explore how Minecraft Education Edition (MEE) can be used as a digital learning resource to create learning contexts in which generic and subject-specific competencies can be developed in interaction.

Generic competencies, often called 21st-century competencies, play an important role in fostering analytical and critical thinking, creativity, and problem-solving in children (Binkley et al., 2012). Dolan (2020) points out that 21st-century competencies should not be an end in themselves but can act as a framework for teaching. Minecraft, often referred to as digital Lego, gives participants an unlimited number of building blocks to create buildings and other visual structures. MEE is a version of this game adapted for use in schools. The basis for this article is a project that started in autumn of 2017 at a City University in Norway in which student teachers with specializations in social studies for 5th–10th grade used MEE to reconstruct historical environments. The article addresses the following research question: How can Minecraft be used in teaching social studies to develop generic and subject-specific competencies?

Enabling historical empathy

To understand the actions of the people who lived in the past, we must have some knowledge of the framework and conditions within which they acted (Lund, 2020). Hatlen (2020) refers to the English tradition of history didactics and explains the concept of "historical empathy" as "understanding how the people of the past saw their world at different times, and why they acted as they did" (p. 147). Like the concept "historical empathy" is the concept "taking [a] historical perspective," described by Seixas and Morton (2013) as:

> [...] considering the different "things" that made up their everyday living – technologies, clothing, housing, food – as well as the landscape of their communities and settlements; [...] ideas and belief systems through which they made sense of it all (p. 138).

The people of the past, like us, acted on the basis of emotions, beliefs, and ideologies, so taking a historical perspective means taking on multiple perspectives. A core element of the Norwegian curriculum is historical empathy (DoE, 2020).

According to Yilmaz (2007), historical empathy can involve elements of emotion but is mostly an intellectual exercise of reconstructing the past through the systematic study of historical contexts. Creating micro-stories about people from a period of the past provides an opportunity to take multiple perspectives and can serve as a bridge to understanding the features of society in that period (Kvande & Naastad, 2020). Roleplaying games and simulations give students access to historical situations or, events as though they were still happening (Lund, 2020). With this roleplay, the historical actors have several possibilities for action within a structural and contextual framework. Lund claims there is "much to suggest that simulation is little used by history teachers, especially the large selection of computer simulations" (2020, p. 127). Probable reasons for this are that teachers find simulations time-consuming to use and difficult to adapt to the classroom (Lund, 2020). This paper will address this gap by using MEE for rebuilding a local context of the industrial revolution and experience it through a roleplay.

Minecraft as a digital learning resource

In the past five years, increased interest in the use of MEE in educational settings has been reported. MEE can increase motivation and creativity and provide opportunities for collaboration in the classroom (Lorence, 2015; Callaghan, 2016). Dikkers (2015) believes that Minecraft's popularity has great pedagogical potential and highlights its benefits in areas such as problem solving, motivation, and commitment in addition to learning academic topics (pp. 110–111). Jensen and Hangøj (2019) point out that MEE creates new ways of participating (p. 361) and changes teacher-centered activities to student-centered activities. Researchers have investigated the use of MEE in subject-specific competencies within language, mathematics, science, and social studies (Jensen & Hangøj, 2019; Lorence, 2015).

Games engage students in and out of school and contribute to flexible teaching, but competition and frequent trial and error approach within games can hinder reflection and learning (Kluge, 2016). Kluge (2016) states that computer games must have a high degree of pedagogical structure and give students opportunities to work with subject-specific concepts to turn commitment to play the game into learning outcomes. Gabriel (2016) points out the need to include digital game–based learning in teacher education to increase student teachers' competence in incorporating digital learning aids like games into their teaching (p. 35). Previous research has shown that few studies examine the use of MEE in teacher education (Egebert & Borysenko, 2019). Callaghan (2016) found that the teacher's active participation in the game is important for students' commitment and motivation. However, Kuhn and Stevens (2017) point out that many teachers are reluctant to use Minecraft because they know less about computer games than their students.

Common understanding through intersubjectivity

This article adopts intersubjectivity (Mead, 1910; Rommetveit, 1976) and dialectics (Vygotsky, 1986) as overarching theoretical concepts. Intersubjectivity can be described as a subprocess of collaborative learning (Stahl, Koschmann & Suthers, 2006; Fugelli, 2012). Rommetveit (1976) defined intersubjectivity as a psychological process that arises between individuals by creating a common understanding (Rommetveit, 1976). Creating a common understanding is essential for developing knowledge together (Fugelli, 2012) and is a central component of computer-supported collaborative learning, both among students and between students and teachers (Ludvigsen & Mørch, 2010). Through intersubjectivity, a group creates a common social awareness (Mead, 1910), which is developed through communication, collaboration, and negotiation (Rommetveit, 1976; Ludvigsen & Mørch, 2010). According to Mead (1910), we create history through communication with others, using a technique he referred to as reconstruction, a process that emerges in the present. Rommetveit stated that intersubjectivity is a social world temporarily shared between individuals, but which can never be completely shared because it is a generalization of different individuals' experiences (Rommetveit, 1976). The intersubjectivity partially developed in a student group needs a driving force to develop into a common knowledge object (Fugelli, 2012); for this driving force, we use the dialectical method (Vygotsky, 1986). In our case, this means setting up tensions between subject-specific and generic competencies and structuring the learning process into three steps. Mørch, Mifsud & Eie (2019) developed a model to apply processes in practice, focusing on the gradual, knowledge-based development of a common understanding (object of knowledge) through intersubjectivity. The three steps of this model are introduction, reconstruction, and transformation. In this work, we applied this model in three rounds of design-based research.

Method and case design: The industrial breakthrough in Minecraft

The main method used to organize this study was design-based research (Brown, 1992) with an emphasis on interventions over three-week periods in three semesters (autumn 2018, spring 2019 and autumn 2019). A total of 146 student teachers followed this topic during the study period. The student teachers were going to use MEE to teach in the classrooms. MEE was used to reconstruct buildings and events of the industrialization period as part of the in-depth study of the industrial breakthrough around 1840-1890, with emphasis on global history and location-specific knowledge of the Aker river area. Based on feedback from previous iterations, the intervention was readjusted several times. Data were obtained via, screen recordings of group work, qualitative interviews, and student-produced films of the roleplay in MEE. The informants were recruited on a voluntary basis. See Table 1 below for an overview of the data we report on.

Table 1: An overview of the data reported on in this article

Data sources	**Amount of data**
Interviews with student teachers	Total numbers of participants = 3
Screen recording of the groups' construction in MEE	2 hours of screen recording
Student-produced films of roleplaying games	25 movies (3–4 minutes per movie)

A thematic analysis (Reichertz, 2014) was conducted of the interviews. The screen recordings show the students' screens and speech while they built. When analyzing the screen recordings, we looked especially for the use of sources, collaboration, and problem-solving abilities. When analyzing the roleplay films, we looked particularly at how subject-specific knowledge of the industrial breakthrough, such as the living conditions of this period, was expressed through context (MEE staging) and conversation between the avatars. For the thematic analysis, we used a combination of data-driven and theory-driven approaches, also referred to as the abductive approach (Reichertz, 2014). The three phases of introduction, reconstruction, and transformation describe the teaching process: first, we (the teachers) introduced the knowledge domain (subject-specific knowledge), then the students created their own reconstructions in MEE and in a written script document, and finally, they transformed the reconstruction and events into a film.

Data and analysis

The data are presented and analyzed for each of the three phases described above: We use empirical data from the Canvas Factory along the river Aker to illustrate our findings. The Canvas Factory started producing canvas for sailing ships in the early phase of industrial breakthrough in Norway.

Introduction

The first phase was to introduce subject-specific knowledge. The students spent time orienting themselves in the subject matter about the industrial buildings and the business associated with them, which had changed over the years. On campus, the students received a more detailed lecture about the buildings' architecture and the events associated with them during industrialization. The teacher then prepared an excursion along the river Aker, in which the students were given the responsibility of presenting their respective buildings to the other participants. During the excursion, the student teachers had the opportunity to take pictures and explore the building and their surroundings (Figure 1). The students gained access to historical sources that dealt with living and working conditions in addition to their own online research. The student teachers were introduced to MEE at the beginning of the intervention period. However, at least one student in each group had previous experience with MEE.

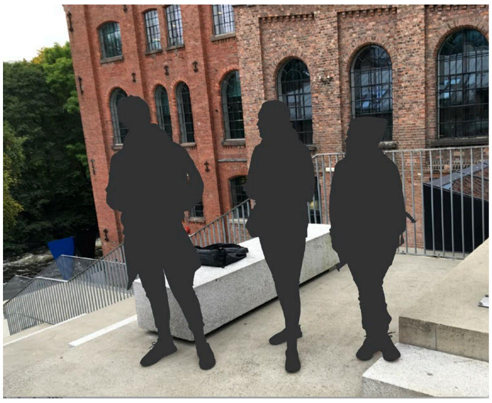

Figure 1. A picture of student teachers in front of the Canvas Factory during the excursion along the river.

The excerpt below is from an interview about how the student used different sources to learn about the Canvas Factory.

Student: We looked at old pictures and we just had to use our imagination to envision how we thought it [the Canvas Factory] was then [. . .]. We also looked in old books to get an overview. But it was difficult to find out, especially at the Canvas Factory, because it was much smaller before (in the industrial age), now it is much larger due to later extensions of the building [. . .] what it looked like in the very beginning, we found a picture that represented it quite nicely, so we got a pretty good overview [. . .]

The student elaborates on his use of different sources to gain knowledge of how the Canvas Factory looked in the industrial age. Next, the students listened to the subject teachers, searched for information on the Internet, distributed tasks among themselves, and planned the next phase. This can be understood as the beginning of the process of building intersubjectivity (common understanding); at this stage, the intersubjectivity is low or vaguely defined. We can see a parallel to Sfard's (1998) acquisition metaphor, as the students were concerned with acquiring knowledge of subject concepts, gaining knowledge of the building through historical sources, teaching, and going on the excursion. This work prepared the students for the later phases.

Reconstruction

In this phase, the student teachers were tasked with reconstructing the buildings as authentically as possible in MEE. Alongside the construction, the students developed scripts for roleplay about living and social conditions.

Reconstruction of buildings

The teachers developed an empty world (Figure 2a) with sites ready for construction along the river. Figure 2b shows how the students reconstructed and built the Canvas Factory in MEE.

Figure 2. Reconstruction of buildings in MEE: a) Empty world (site) made by the subject teachers (left) and b) the building constructed by a group of student teachers tasked with modeling Canvas Factory (right).

At the start of the reconstruction phase, an interesting pattern was revealed: group members experienced in MEE took initiative and control over the building process. The students with less experience received training from the more experienced, as revealed in the following interview excerpt:

Student: The other two I worked with had no experience with Minecraft, so it was in a way my job to teach them to play Minecraft and be leader for the construction in Minecraft and the organization of the activity. But they (the other student teachers) worked very hard to build things. I had to explain it for them, like that this area here should have this kind of stones, and you have to build using that kind of pattern, and things like that. It was very alright to work that way. During the roleplay and scriptwriting, it was the others who created the dialogue.

The students agreed on the dimensions, building materials, and design of individual elements in the building and then distributed the construction work. They often collaborated on the most complicated parts of the building, such as roofs and windows. The excerpt below illustrates the need for collaboration when reconstructing the more complex elements of historical buildings in MEE, in this case, the factory building roof.

Student: When we started building and shaping the roof, someone said: "The roof will be very high." So, we looked at it and agreed, because it got very high, so

> then we flattened it [the roof]. In the game [MEE], you have stair blocks, and when you use them on top of each other, it becomes a very pointed roof. As a result, instead we used flat half blocks and a regular block [. . .], and then it became a flatter roof. [. . .] and it matched better with the picture as well.

The following excerpt is from an interview with a student who reconstructed the Canvas Factory.

> Interviewer: How did you solve the task of building the Canvas Factory?
>
> Student: We had to find out information about the Canvas Factory, and we were on an excursion along the river. We had a presentation about the factory when we walked along the river, so then we got that prior knowledge there and talked about strikes and poor working conditions and things like that. We also saw the building there. [. . .] Later, we used Google Earth to zoom in on the building to see what it looked like, but there is an extension there [in the new Google picture] and a staircase on the side that was not there before. Earlier [during the industrial age], it was just a plain [staircase].

Figure 3. Reconstruction of the staircase inside Canvas Factory.

The two previous excerpts describe the reconstruction process, highlighting two typical situations in which generic competencies and subject-specific knowledge were applied. First, the students put great effort into searching the MEE inventory for the right building blocks to use, and they regularly checked their own buildings against sources, including historical images, floor plans, and digital maps. Second, when the groups encountered problems in the construction process, they searched for more information. To figure out how the Canvas Factory looked when it was founded in 1858, the students had to search for historical pictures and drawings in books and online. The students compared different sources of information and discussed them to come to an agreement of how the building might have looked. This process parallels the process of building intersubjectivity (Rommetveit, 1978), in which students enter discussions and develop a common ground.

The reconstruction phase facilitated the development of generic competencies, such as creativity, problem solving, collaboration, and division of labor. When reconstructing the building, the students discussed the different parts of the construction process. This parallels Sfard's (1998) participation metaphor, which foregrounds participation in the collaborative building process. In the data presented above we see a tension between generic and subject-specific skills: the students worked to develop parts of the building both in parallel and together. The students contributed with their parts (walls, windows, doors, etc.) to create a whole factory building along the river, which in turn set the framework for the individual parts. This tension is linked to the lack of subject-specific knowledge. When detailing the staircase in the building, which was not shown in the original pictures, the students had to be creative. Generic competencies were therefore more dominant in this phase, contrasting with the subject-specific knowledge driving the process forward (i.e., through the need for more detailed knowledge). The development of generic and subject-specific competencies is interdependent: the whole (which is a set of relationships among parts, Figure 2b) is related to the use of domain-specific knowledge, and the parts in isolation draw on generic skills, such as creativity and information seeking (Figure 3). The two types of competencies are in a dialectical relationship (Vygotsky, 1986), which is resolved in phase 3, transformation.

Reconstruction of historical events

To reconstruct historical events and develop a realistic script, the students sought historical sources that went into depth about working conditions, power relations, and living conditions. When researching working conditions, one student came across an interview with a former employee in one of the industrial buildings, in which the worker uses the term "black pudding on Fridays"—which the student connected to their present-day "Taco Fridays." Tacos are a typical Norwegian Friday dinner dish. The following excerpt elaborates on this connection:

> Student: We refer to the present and we called it black pudding Friday instead of taco Friday. We used humor. [. . .] When it comes to problem solving, such as reconstructing a building without having the correct measurements, but at the same time getting the whole of the structure to resemble the actual building, collaboration, problem solving, and creativity are fundamental.

In the literature, this is referred to as anachronism or prolepsis. In Rommetveit's (1976) work on intersubjectivity, such formulations are considered a technique for bringing past conversations and common understandings forward in time. This linking of black pudding and taco Fridays can be seen as an anachronistic or proleptic play on words, connecting the past, the present, and an anticipated future with the aim of increased intersubjectivity.

Historical empathy is not about free imagination but about developing an understanding of a historical context via sources (Hatlen, 2020). To achieve historical empathy, the historical context must be reconstructed. The student groups based their reconstruction on sources, but several students told us they also took artistic freedom, using their own knowledge to adapt the end result. Several students expressed personal empathy for the reconstruction as they began to feel a sense of ownership of the building's history. Data from the Canvas Factory indicates that the students activated both feelings and reasoning by taking on different perspectives and life experiences in the roleplay, such as gender and class membership, which is related to historical empathy.

In the reconstruction phase, the students became participants in a community in which collaboration skills, problem-solving abilities, and creativity paid off. In using trial and error in in the building process (placing, destroying and rebuilding blocks in MEE) the students negotiated towards a shared understanding of the historical building connected to different artefacts: the MEE building and the role play script, implying that intersubjectivity gradually materializes, but partly fragmented.

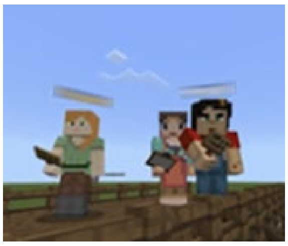
Transformation

In the third phase, the students used what they had made, the building and script, to make a film showing their learning in a compact format. Two main findings emerged in the transformation phase: 1) how the students co-created a shared object of knowledge through roleplay, and 2) how the students connected the historical knowledge in the film to their own lives. These two points will be elaborated in this section.

Below are stills from a student group's film of their roleplay in the historical context of the Canvas Factory in MEE. The film shown in Figure 4 is set in 1889 and begins with a dialogue between the female workers in the factory, the director, and a representative for the workers' rights. In the opening scene, the female workers receive a scolding from a male head worker who tells them to work faster. This frustrates the women, who complain to the factory manager. He dismisses their complaint and says they are easy to replace. In the second

Female worker: Mr. Director! The men in here do nothing but scold and picking on what we do. The work we do is heavier than theirs and the air we breathe actually makes us sick.
Director: That's actually how it is here. I have done nothing but take you under my wings. You can be replaced in no time.

Agitator: Mr. Director! It is so that these women have miserable working conditions. Their wages are much worse than those of men. They are not valued for the effort they actually put in.
Director: I stand by what I have said earlier in this case and am not at all interested in negotiating. I do not need them.



Female worker: Then we go on strike. All of us! Then we'll see how your factory production goes.

Figure 4. A series of screenshots and the corresponding dialogue from a film set inside the Canvas Factory.

scene, the female workers call upon a well-known agitator for workers' rights. In the last scene, we see the female workers go on strike:

The four-minute film demonstrates subject-specific knowledge about working conditions, class relations, gender relations, and agitation for workers' rights. The roleplay dives into a limited reality, in which the actors play out written scripts and have certain options for action that depend on the level of detail in the script and creative on-the-spot adaptation. The students' roleplay in MEE has the potential for generalization of experiences to others. The factory workers and factory owners' function as representatives of "many from the same place and conditions in the relevant period" (Kvande & Naastad, 2020, p. 186). The students' roleplay enables them to get closer to historical events, take on different perspectives, and imagine how past events were happening (Seixas, 2013).

In the transformation phase, subject-specific knowledge is foregrounded, while the generic competencies of creativity and adaptation stay in the background. Both competencies can be identified in the film, as illustrated by the dialogue sequences in Figure 4. A transition occurs between the two types of competencies when an actor plays out a prolepsis (Rommetveit, 1976), which shifts the dialogue and the group's common understanding away from subject-specific topics (e.g. blood pudding for industrial workers' dinner) to a generic competency (e.g. adaptation). This shift in turn drives the intersubjectivity forward in time, resulting in a common object of knowledge. Intersubjectivity at this stage is focused, combining a verbal component (the roleplay conversation) and a visual component (the MEE building staging the roleplay). Our data indicates that through phases 1–3, the students gradually developed a common, focused object that ended with the films used in plenum presentations.

Conclusion

This article discussed how MEE can function as a digital learning resource for developing generic and subject-specific competencies in tandem. In the introduction phase, the learners received a professional introduction to subject-specific knowledge and were given access to primary and secondary sources of information. The learners were given multiple opportunities to develop their subject-specific knowledge. In the reconstruction phase, historical buildings and events were recreated in MEE and the learners were given opportunities to develop generic competencies, such as creativity, collaboration, problem solving, design, and adaptation. In the transformation phase, the students' generic competencies and subject-specific knowledge were integrated and transferred to a common knowledge object, in this case, a film of roleplay in MEE. In this phase, the subject-specific knowledge came into focus, while the generic competencies were put in the background. Tensions between the two competencies drove forward the process of creating intersubjectivity. The student teachers dialectically switched between developing generic and subject-specific competencies when using MEE to rebuild the industrial age. This was partly facilitated by the model we used for teaching, but also aided by the tensions inherent in the knowledge domain (historical knowledge) as it is reconstructed using a new digital learning resource.

The implication of this paper is that Minecraft may be explored in an educational setting as a digital learning resource that facilitates active learning processes by making history more engaging. Learners are given the opportunity to contextualize the past and imagine how historical actors lived, often under very different conditions than those under which we live today.

The Role of Bridging Practices in Expansive Learning Processes

Susannah C. Davis, University of New Mexico, scdavis@unm.edu

Abstract: Increased accountability policies and pressures have forced teacher education programs in the United States and elsewhere to use various forms of outcome data in new and expanded ways. I employ an activity-theoretical framework for organizational learning known as expansive learning to examine how three "high data use" programs developed new work practices in order to both comply with external policies and also serve locally-constructed goals. Findings highlight similar and different ways these programs navigated organizational change by re-mediating their activity systems. This study extends previous work on organizational learning by illuminating relational *bridging practices* that facilitated expansive learning despite tensions, setbacks, and disturbances created as new work practices emerged in response to changing conditions. Through bridging practices, these programs developed co-constructed collective motives related to data use, common knowledge, distributed expertise, and a sense of collective agency and shared responsibility; these became cultural resources that supported expansive learning efforts.

Keywords: Organizational learning, teacher education, leadership, activity theory, case studies

Introduction

In teacher education and other programs in higher education in the United States, new and intensifying pressures surrounding data use for external accountability and program improvement are emerging from several directions, including escalating public scrutiny of teacher preparation, new federal and state mandates, and new Council for the Accreditation of Educator Preparation (CAEP) standards (Cochran-Smith et al., 2018; Wilson, 2014). As programs are expected to engage with outcome data in new and different ways, program leaders are tasked with balancing data use as required by accountability mandates and data use that willingly engages program members and is focused on locally-oriented goals constructed with input from various internal stakeholders (Davis & Peck, 2020; Cochran-Smith et al., 2018; Peck, Gallucci, & Sloan, 2010). Data use for compliance and, especially, for inquiry purposes requires motivating and engaging faculty, supervisors, and administrators to participate in collaborative inquiry, data analysis, and decision-making activities and to draw on those activities to make and evaluate program changes using multiple sources of evidence; in short, it requires organizational learning and change.

In order to better understand how teacher education programs (TEPs) situated within institutions of higher education undergo such collective learning processes, I studied three "high data use" TEPs with exemplary commitments to using data for program improvement (including what was necessary to comply with state and accreditation agencies, but moving beyond that to ensure that data use served locally-constructed goals). I drew from a conception of organizational learning based in activity theory known as expansive learning (Engeström, 1987, 2001; Engeström, Kerosuo, & Kajamaa, 2007; Engeström & Sannino, 2010) to examine how these three programs, located in diverse institutional and regional settings in the United States, navigated increasing data use policies and practices over the course of two years and learned in individual and collective ways in the process. Findings highlight both similarities and differences in how faculty and administrators in these TEPs re-mediated their activity systems and developed new data use processes that progressed beyond required accountability and accreditation policies to serve co-constructed local goals. While studies of expansive learning generally focus on structural and systemic changes (Engeström et al., 2007; Engeström & Sannino, 2010), this study extends this body of work by illuminating the role of interpersonal *bridging practices*—which are relational and organizational practices that help resolve tensions and disturbances created as new work practices develop in response to internal and external conditions—in continuing expansive learning. Over time, these bridging practices facilitated co-constructed collective motives related to data use, common knowledge, distributed expertise, and a sense of collective agency and shared responsibility; these became cultural resources that supported expansive learning.

Theoretical framework

In order to examine organizational learning processes, I drew on a framework of organizational learning called expansive learning, based in cultural-historical activity theory (CHAT). Expansive learning considers organizational learning to be an iterative, evolving process of development in which interrelated, interdependent elements of an activity system are re-mediated through collective activity in order to better serve a collective motive, known as the *object* (Engeström, 1987). As a sociocultural theory of learning with roots in Vygotsky's (1978) work, CHAT attends to the roles of a system's participants, cultural norms, policies, social structures, and conceptual and material tools in object-oriented learning (Engeström, 1987, 2001; Roth & Lee, 2007). This is a particularly helpful theoretical framework for understanding organizational learning related to data use for program improvement and accountability, as such data use requires attending to the context, including organizational routines of data interpretation and use, individuals within the system, and the tools used to mediate interpretation of data (Spillane & Miele, 2007).

In CHAT, individual and collective action and learning within an activity system is understood in relation to the system's collective motive (i.e., *object*) and the participants (i.e., *subjects*) who are motivated by this object. Material and conceptual *tools* and resources also mediate the system's activity, as do the *rules* and *division of labor* within the system's *community*. These interactive components of an activity system guide analysis of learning and development within a focal system (Engeström, 1987; Roth & Lee, 2007); in this case, a TEP aiming to use data for program improvement and accountability.

CHAT highlights the role of contradictions, which are historically-laden tensions within and between components of the activity system, in driving change and learning (Engeström, 2001). These contradictions manifest through disturbances, innovations, dilemmas, conflicts, or double binds in the activity system (Engeström & Sannino, 2010). Development and learning occur as individuals and groups attempt to resolve contradictions through the development of new tools, practices, or social relations aimed at better aiding an evolving object. These developments and new practices lead to changes or expansions of the object through a process of *expansive learning*. In processes of expansive learning, contradictions unsettle existing practices and potentially motivate and guide re-mediation of the activity system in ways that further collective learning and development. However, contradictions do not necessarily lead to expansive learning; expansive learning cycles may be broken or abandoned (Engeström, Keruso, & Kajamaa, 2007). Engeström and colleagues (2007) found that there were some times when efforts to "bridge" the discontinuities leading to "breaks" in a cycle of expansive learning were successful in continuing organizational development towards an expanding object, while at other times these attempts were not successful. In these cases, expansive learning processes were abandoned and an alternative object was embraced.

CHAT's conception of expansive learning provides a lens that facilitates examination of collective goal-oriented activity and learning. I drew on the expansive learning framework to analyze how three TEPs situated in different state, local, and institutional contexts within the United States experienced and responded to new policies and pressures around data use, including whether and how contradictions in these systems led to new work practices or a new, expanded collective object and new activities aimed at that object. See Davis (2021a) for an extended expansive learning analysis of these three programs. In this paper, I provide an overview of this analysis in order to focus on what these findings suggest about the process of expansive learning, and the organizational and relational practices that leaders and others who care about collective development towards a particular object can do to support individual and collective learning and development through expansive learning processes. This investigation was guided by the following research questions:

1. What is the role of contradictions in expansive learning?
2. What practices and resources serve to bridge or support expansive learning efforts?

Research design and methodology

I employed a qualitative multiple case study design (Merriam, 2009; Stake, 2006) in order to analyze individual and collective practices supporting or constraining expansive learning. A multiple case study design facilitated in depth data collection and analysis while also supporting contextually-rich comparative analyses (Merriam, 2009; Stake, 2006). This study's three focal cases were strategically chosen for their organizational commitments to data use, as well as the diversity of their contexts within the United States (see Table 1). The cases were situated in different institutional and state contexts; they all faced national and accreditation-related accountability demands, with some differences in the pressures coming from state and institutional levels.

Table 1: The three cases

Institution (Pseudonym)	**Institutional Size**	**Institutional Type**	**Region**	**Annual TEP Graduates**	**Outcome Measures Used**
Glenville State University (GSU)	28,000	Doctoral Universities: Higher	Southeast	800	Value-added measures; edTPA; graduate

		Research Activity			satisfaction; employer satisfaction
Milford College (MC)	5,000	Master's Colleges & Universities: Medium Programs	Midwest	90	edTPA; employer satisfaction; graduate satisfaction
University of Longview (UL)	20,000	Public Doctoral Universities: Highest Research Activity	West	120	edTPA; employer satisfaction; graduate satisfaction

In order to address my research questions, I analyzed data from two to four site visits conducted at each focal institution over the course of two years. This data included: 82 interviews and focus groups; five day-long observations of collaborative data use activities; and variety of artifacts from each program, including job descriptions, compensation policies, and meeting minutes. Data analysis was ongoing and iterative. I started with an initial round of open coding of all relevant data. Next, I developed a code list based on my initial reading of the data as well as a "start list" of codes from my literature review and theoretical framework. I engaged in multiple rounds of open and focused coding of all data (Miles & Huberman, 1994). The final coding scheme had 21 categories, including categories such as "individual motive/goal", "collective motive/goal", "relational agency", "division of labor/personnel", and "shared responsibility". Shared responsibility was an example of an emerging theme from data analysis, as I noted the ways in which various stakeholders expressed an understanding of joint, rather than solely individual, responsibility for improving the program and better preparing novice teachers in interviews and observations. For example, in a focus group, a faculty member at GSU said, "People are starting to see, going from the style of 'Oh, I know how to do it. I know how to do it better' to: 'You know what? I think *we* can do it best.'" Both during and after the coding process, I employed clustering techniques to consider patterns in the data, compare cases, triangulate data sources, and identify disconfirming evidence or outliers (Miles & Huberman, 1994). I also conducted member checks (Merriam, 2009).

Findings

I employed a cultural-historical conception of organizational learning known as expansive learning (Engeström, 1987, 2001; Engeström & Sannino, 2010) to examine the similarities and differences in the ways in which the three cases experienced and responded to increased pressures around data use (see also Davis, 2021a). Activity systems undergo expansive learning when confronting contradictions leads the collective to a new, expanded object and related new work practices (Engeström, 1987). In a cycle of expansive learning, an activity system grapples with four levels of contradiction:

1) The *primary contradiction* involves tensions between an activity's use value (i.e., the inherent value) and exchange value (i.e., the commercial value)
2) *Secondary contradictions* are concrete manifestations of the primary contradictions that occur between two or more nodes of the activity system (e.g., between the system's rules and the division of labor), which may lead individuals to question or change their practices
3) *Tertiary contradictions* occur with the introduction of new patterns of activity as people attempt to resolve secondary contradictions
4) *Quaternary contradictions* occur between the focal activity system and neighboring activity systems (e.g., between a TEP and local K-12 schools) as the focal activity system innovates and changes their practices (Engeström, 1987; Foot & Groleau, 2011).

This expansive learning analysis highlighted not only salient challenges most, if not all, US TEPs face under the current accountability climate, but also the important role of specific types of organizational and relational practices that served as bridging practices in the process of expansive learning. I first give an overview of the role of contradictions in the expansive learning processes at these three sites, and then describe the bridging practices that fostered expansive learning.

The role of contradictions in expansive learning

Despite significant differences in the three cases' sociohistorical contexts and data use practices, there were also marked similarities in the types of contradictions each program faced and the new activities that were developed to help relieve those contradictions and evolve organizational work practices related to the object of data-informed program improvement. I focus my analysis primarily on the systemic disturbances accompanying the introduction of standardized teacher performance assessments (edTPA) in each program to illustrate some of the most salient similarities and differences among these cases. While all three programs were undergoing numerous changes related to data use during the period of data collection, all three programs had recently begun piloting edTPA.

The primary contradiction: Internal vs. external accountability

The three TEPs in this study were situated in the context of increased competition from alternative route programs, fiscal scarcity, public accountability based on candidate outcomes, and criticism of traditional university-based teacher education. This played out through a primary contradiction (Engeström, 1987) between the object of internal accountability (guided by local values and goals) and that of external accountability (guided by the expectations of state and accrediting agencies, federal entities, and the public). Program leaders and members articulated tensions between the need to comply with accountability policies related to data use in order to prove their (exchange) value, and their desire to use program outcome data (including new sources of data often mandated by state regulatory bodies or national accreditation bodies) for internal program improvement purposes.

Interviews with program leaders at all three sites illuminated how tensions between internal and external accountability goals revealed a double bind. A dean at MC articulated this double bind as "the difference between proving and improving." Program leaders in all three programs exhibited commitments to using data to improve their programs based on local values, but at the same time, they also needed to use data to "prove" their worth to accrediting bodies, state regulatory bodies, prospective and current students, and the general public.

Secondary contradictions: Evolving object related to data use vs. data sources (tools)

As the accountability climate intensified, tensions developed in each of these three TEPs between implementing state and accreditation-related data use policies, which required using many sources of program outcome data to prove program effectiveness, and using data in an inquiry-oriented manner to improve their candidates' learning and their program outcomes. This manifested as a secondary contradiction between an evolving object related to data use for program improvement over data use for accountability and the available data sources (tools) that would support this object. Program members found that some data sources, including performance assessments, were more conducive to inquiry-oriented data use efforts than other data sources, such as value-added measures, which were difficult to interpret at the program or course level (Davis & Peck, 2020).

This tension between the object and available tools was influenced by pressures to use edTPA as it gained increasing popularity as an assessment tool in the field. All three programs began piloting edTPA before it was required by their states, motivated at least in part by their desire to learn how to best use edTPA to serve program improvement goals before the performance assessment potentially became required by external accountability mandates or consequential for candidates. This proactive approach helped maintain a sense of agency and internal accountability as external accountability pressures increased (Davis, 2021a). While the three programs had different relationships with the development of edTPA, their involvement piloting edTPA and providing feedback to the creators fostered a "sense of dialogue" (Faculty/Program Coordinator, UL) and collective agency.

Tertiary contradictions: New vs. old tools and practices

Tertiary contradictions occur as new activities and practices potentially clash with previous versions of those activities and practices (Engeström & Sannino, 2010). As programs began implementing edTPA, tertiary contradictions manifested as conflicts between existing work practices and the demands of this new tool. For example, each program experienced contradictions between new data sources and existing capacities and routines associated with other tools in the activity system used to conceptually and logistically manage data, including data platforms. The programs managed these tensions in ways that depended on their available structures and resources. GSU drew on financial and human resources to create and use a new data platform, MC began researching ways to expand or replace their existing data platform, and UL managed the tension primarily by shifting the division of labor around data sharing and analysis (e.g., creating a new edTPA Coordinator position). Each of these solutions addressed a common issue in ways that worked given their contextual differences. However, any time a new element is introduced in an activity system, even when created to address a contradiction, there are unintended consequences within the system. For example, the introduction of a new shared data platform at GSU precipitated further tensions, including the need for additional human and technical supports that allowed students, faculty, supervisors, and administrators to be able to *use* the data platform for both accreditation reporting and programmatic research and development.

Quaternary contradictions: Managing tensions with other activity systems

Each program experienced contradictions not only within their activity system as new practices conflicted with existing practices, but also between their activity system and neighboring activity systems (Engeström & Sannino, 2010; Foot & Groleau, 2011). These programs experienced quaternary contradictions between their emerging practices and their relationships with state policymakers and accrediting bodies, the K-12 systems they worked with (e.g., schools that candidates did fieldwork in), the makers of edTPA, and with Pearson, who was contracted to do the external scoring of edTPA and support scale-up efforts. These contradictions, particularly with state policymakers, accrediting bodies, and edTPA/Pearson, manifested in concerns about institutional autonomy and their ability to challenge a "powerful… bandwagon" (Faculty, GSU).

In order to maintain collective agency and autonomy, members of all three programs (particularly program leaders) acted as "watchdogs" (Faculty, GSU), advocating within and outside their program for their own longstanding and emerging beliefs about the role data and assessments have to play in defining and evaluating teacher quality, especially for credentialing purposes. These programs were determined to be part of larger state- and national-level conversations about teacher education and evaluation of teacher quality. They were deeply committed to internal inquiry about how to best serve their own students and to improving their own programs towards locally developed and articulated goals.

Bridging individual and collective development in activity: Developing relational practices for expansive learning

Engeström and colleagues' (2007) identified the role of bridging actions as attempts to resolve contradictions in ways that continue rather than abandon expansive learning processes when there is a threat to their persistence. They primarily identified bridges as systems-level decisions and actions (e.g., adopt a new training system); the authors did not examine or define the role of individual or interpersonal practices in maintaining a cycle of expansive learning. Institutional structures and resources do not create change on their own; change and learning also depend on people's engagement in actions and activities. In activity theory, there is a crucial but undertheorized relationship between individual agency and organizational development and change. Theoretical and empirical research in activity theory and expansive learning has primarily focused at the level of collective and systemic phenomena, often ignoring or underspecifying the role of individual learning, identity, agency, and motivation (Billett, 2006, 2008; Edwards, 2007, 2010; Engeström & Sannino, 2010). My analysis of expansive learning processes in these three TEPs suggests that relational bridging practices played a key role in addressing tensions and conflicts that came up during the process of organizational change and expansive learning.

In these programs, shifting the allocation of structural resources and program policies was helpful but insufficient in motivating and sustaining engagement in data use. Program members also needed to see the value of data use work for themselves and the program before participating. It was particularly important for program members to see the utility of data use *beyond* its necessity for external accountability. This required relational practices that attended to and reinforced "the human factor… [that] drives us to do our best work" (Program Administrator, GSU). Relational *bridging practices* that linked and supported individual and collective motives, agency, knowledge, expertise, and responsibility encouraged and sustained program members' engagement in data use work that furthered programmatic goals. These bridging practices are described in detail in Davis (2021b) and summarized below.

Bridging individual and collective motives

Program members only engaged in data use and related decision-making processes in authentic and sustained ways once they believed in its utility for themselves and the program. In order to broaden participation, leaders at all three programs attended to the ways in which individual motives might align with collective, programmatic goals. One strategy program leaders employed was the construction and articulation of organizational narratives (Edwards, 2010) that *reframed accountability* by emphasizing how data use practices could help evaluate and improve internally defined, co-constructed program goals rather than externally defined, compliance-oriented goals (Davis, 2021b; Davis & Peck, 2020).

Over time, with continued articulations of these inquiry-focused organizational narratives, people became more invested in the evolving, increasingly collectively-constructed program goals. Most program members found ways to work collaboratively "together with a common goal" (Supervisor, UL). This did not necessitate that all program members participate in exactly the same ways, or hold the same views about data use. At UL, participants noted how the program director trusted faculty, supervisors, and staff to "decide their agendas" (Faculty, UL) within the context of shared, co-constructed program goals.

Bridging individual and collective agency

The shifting political environment for teacher education threatened a potential loss of individual and programmatic agency. Tensions also arose between the desire for individual agency (for example, wanting authority over all aspects of a particular course) and collective agendas around data-informed program improvement. As program leaders worked to address these tensions and related individual resistance to change by listening and responding to individual needs and concerns, program members began to see and appreciate a growing sense of collective agency.

In a focus group at GSU, faculty discussed the "tsunami of expectations" associated with external accountability pressures and articulated how alone, one person would "get knocked over in a heartbeat," but "when you're all in it together" they don't get "battered around by myself". Collective action allowed them to "stand up to that wave" (Faculty focus group, GSU). The emergent collective strength resulting from collaborative, goal-oriented data use work motivated continued participation and fostered a proactive stance towards accountability. This facilitated a sense of collective agency despite increasing external regulations.

Bridging individual and collective knowledge

Increased inquiry-oriented collaboration around data use, including cross-role collaboration (e.g., tenure-track faculty, instructors, supervisors, and administrators working together, including across disciplinary boundaries), resulted in the development of co-created common knowledge (Edwards, 2010) and a common language of practice (Peck et al., 2010) among program members. The TEP director at UL argued that "one of the things that makes us really strong is that we do capitalize on the knowledge that… exists within the program. It's collective knowledge. It's not my knowledge."

Bridging individual and collective expertise

Program leaders and members also worked to identify individuals' strengths and areas of expertise and find ways for them to constructively contribute to collective data use work. This led to a network of distributed expertise that encompassed program members across roles. A supervisor at UL stated, "Each of us has our own strengths… there's really a web, a network [of program members], that is continually moving."

Networks of expertise grew not only within the three TEPs, but also across activity systems. For example, programs across the Southwest state GSU was situated within, including GSU, began engaging in cross-institutional discussions and research related to data use and accountability policies.

Bridging individual and collective responsibility

Study data indicated a growing sense of shared responsibility for program outcomes. Through cross-role, cross-disciplinary collaboration, stakeholders began to understand and develop "an ownership of the program and the product in the program." This involved looking "beyond your piece of the pie to what's coming out in the end." (Program administrator, GSU). There was ample evidence across cases that faculty, supervisors, and administrators were increasingly connecting their individual work and role in the program to how prepared graduates were at the end of the program based on program outcome data. Despite some faculty members' initial resistance to edTPA, the vast majority found that the holistic nature of edTPA (i.e., an assessment that wasn't tied to a particular course, but rather a candidate's overall learning in the program) allowed them to see and appreciate their own role in the bigger picture and feel increasing individual and collective ownership for program outcomes.

Cultural resources built by bridging practices

The co-constructed collective motives, collective agency, common knowledge, distributed expertise, and sense of shared responsibility that interpersonal bridging practices fostered over time became important cultural resources that program members could increasingly draw on to improve collaborative data use efforts and further organizational learning.

Figure 1 articulates the relational strategies and resources that supported organizational change efforts. The overall context is an activity theory framework. The components of the activity system and the relationships among those components provide structural and organizational supports for expansive learning. Within the activity system's expansive learning process, the bridging practices described above mediate and connect the subjects and the object of activity. Over time these bridging practices, along with the structural resources that support individual subjects' engagement in joint work within the activity system, have the potential to lead to cultural resources that include: the co-construction of collective motives related to the object of activity, collective agency, common knowledge, distributed expertise, and a sense of shared responsibility. These cultural resources further support expansive learning efforts.

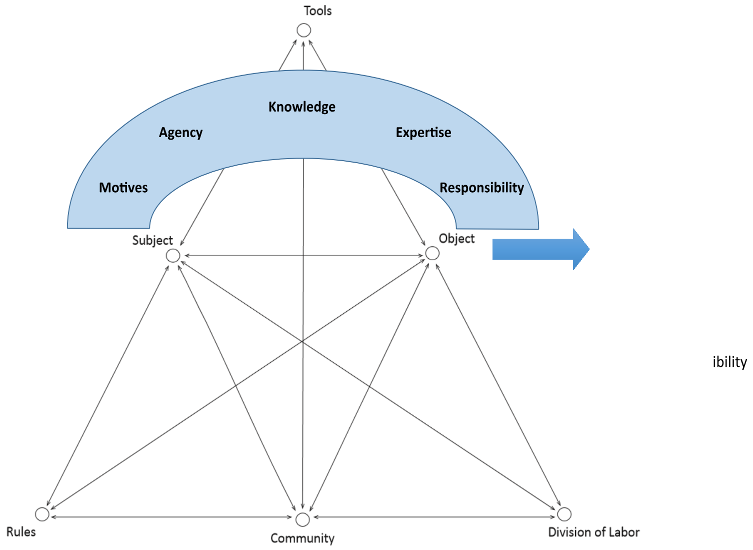

Figure 1. The role of bridging practices in expansive learning

Discussion and implications

Findings from this study suggest that the process of developing and sustaining collaborative data use practices through expansive learning required simultaneous attention to interpersonal, organizational, and cultural dimensions of the change process. This included practices such as articulating how individuals and programs might benefit from the collective agenda; reframing accountability by emphasizing data use for internal program improvement goals; strategically involving program members in cross-role collaboration; creating ways for individuals to co-create a collective vision for data-informed program improvement; setting up collaborative structures to facilitate data use and decision-making activities; developing incentives and concrete supports for individuals to participate in those collaborative activities; adjusting program norms to emphasize and reify the value of collective work; and continuously revising programmatic data use practices based on continually co-constructed collective goals.

While these are complex and demanding processes, these findings can offer guidance to leaders within and beyond teacher education facing similar challenges. This study offers new insights about managing motivational and interpersonal aspects of organizational change and expansive learning. While this study includes a relatively small number of programs, the fact that thematic findings were consistent across programs that vary significantly in size, mission, and state policy context suggests that they may be of relevance and value to others interested in facilitating individual and organizational learning within educational programs and institutions (Merriam, 2009; Patton, 2003).

Most research on organizational change from an activity theory perspective focuses primarily at the level of collective activity as it relates to organizational structures and resources. These studies contribute important insights about processes of organizational change, but often ignore or underspecify the important role and contribution of individual learning, identity, agency, and motivation (Billett, 2006, 2008; Edwards, 2007, 2010; Engeström & Sannino, 2010). This study expands on the undertheorized role of individuals and relationships within processes of expansive learning (Engeström et al., 2007). In this study, I connect institutional structures and resources that support organizational change with relational strategies and actions (bridging practices) that motivate engagement and foster co-constructed joint goals, collective agency, common knowledge, distributed expertise, and shared responsibility. These bridging practices and the cultural resources they created became the driving force of expansive learning for these programs as they navigated a changing accountability landscape. As learning scientists increasingly partner with organizations to address persistent problems of practice (Fishman, Penuel, Allen, Haugan Cheng, & Sabelli, 2013), these findings provide insight into practices that facilitate individual engagement and learning in processes of organizational learning and development. As TEPs and other educational institutions become more adept at managing the relational as well as the structural aspects of organizational change, they will be better able to motivate and facilitate both individual learning (of, in the case of teacher education, faculty, teacher candidates, and, ultimately, students) and collective organizational learning.

Teachers' Aesthetic Judgments of Classroom Events

Jennifer Richards, Bruce L. Sherin, Mari Altshuler
jrichards@northwestern.edu, bsherin@northwestern.edu, marialtshuler@u.northwestern.edu
Northwestern University

Abstract: This paper introduces and articulates the contours of a novel component of teacher noticing and thinking—teachers' *aesthetic judgments* of classroom events. By aesthetic judgments, we refer to teachers' rapid recognition of particular classroom events as having a certain character or quality, such as students being highly engaged or having a "good" conversation. Drawing on a definition from diSessa (1993) of an aesthetic as a loose knowledge system that operates in a data-driven manner, we highlight how such judgments appeared and functioned in the context of teachers selecting video clips from their own classrooms to share in an online professional development course. We describe a range of aesthetic judgments evident in this context to illustrate what aesthetics may involve and sound like in practice and to highlight domains in which teachers may draw on influential aesthetics. We conclude with consideration of related empirical and theoretical issues.

Keywords: aesthetics, teacher noticing, teacher thinking, video-based professional development

Introduction

Over the last two decades, research on teacher noticing has been concerned with how teachers parse and make sense of complex classroom events (Schack et al., 2017; Sherin et al., 2011). Accounts of teacher noticing commonly emphasize at least two key dimensions of noticing, often considered and analyzed as distinct dimensions—what teachers attend to within classroom interactions, and how teachers interpret or reason about what they attend to (see van Es & Sherin, 2021, for a recent review). However, studies continue to explore and debate how these dimensions relate to each other and the extent to which they are separable (e.g., Barnhart & van Es, 2015; Sherin & Star, 2011; Walkoe et al., 2020), particularly if conceptualized as cognitive processes. A range of research and teacher learning efforts have sought to both understand the nature of teacher noticing and support its development through intentional work with video recordings of classrooms, such as having teachers write analyses and reflections about videotaped classroom events (e.g., Barnhart & van Es, 2015; Superfine & Bragelman, 2018; Walkoe et al., 2020) or watch and discuss videos in arrangements like video clubs, in which groups of teachers meet to examine videos recorded in the classroom of one of the participating teachers (e.g., Sherin & van Es, 2009; Stockero et al., 2017; Walkoe & Luna, 2020).

The work reported in this article departs from prior work on teacher noticing by focusing on a unique aspect of teachers' workflow with respect to video. Namely, we looked closely at teachers' noticing processes as they selected clips from video that they captured in their own classrooms. This was done in the context of an online professional development course, for the purpose of sharing and discussing with other teachers.

Working within this novel context drew our attention to phenomena that we believe are not well-captured by prior research on teacher noticing—phenomena that we now call *aesthetic judgments*. In brief, when engaged in selecting clips, teachers seemed to make rapid judgments about what they saw in their classroom videos, highlighting particular parts as reflecting particular characteristics or qualities (e.g., where students were really engaged, where the conversation was "meaty"). These judgments blurred the lines between attending and reasoning, in that the very "noticed-things" (Sherin & Star, 2011) integrated inferences and characterizations. These rapid judgments were instrumental in understanding teachers' selections and selection processes in this video-based professional development opportunity in which teachers had agency over what to share. Further, we have come to believe that teachers' selection processes provided a window into an important, underspecified component of teacher thinking.

The purposes of this paper are to introduce the idea of an aesthetic judgment as applied to teachers' parsing of classroom events, and to provide the reader with a sense for the kinds of aesthetic judgments displayed in the context of our course. We do this with illustrations drawn from our data corpus. We discuss this corpus and the context in which it was collected in the next section. Then, we explain what we mean by an aesthetic judgment, situating this new construct. After that, we present, with examples, a range of types of aesthetic judgments seen in our corpus. We finally conclude with a discussion of empirical and theoretical issues, questions, and next steps with respect to the study of teachers' aesthetics as a focus of research.

Study context

Our study of teachers' aesthetic judgments occurred in the context of a short, online course on mathematical argumentation in kindergarten through second grade, adapted from a longer course designed by Lomax et al. (2017). In the course, participating teachers were asked to try a series of argumentation activities with their students, videotape the conversations that occurred, and select a 3-4-minute portion of each conversation to share and analyze with peers in the course. For instance, one argumentation activity involved showing a set of four images that differed in multiple respects and inviting discussion of "which one doesn't belong" and why. A second argumentation activity (reflected in the example in Figure 1 below) asked teachers to lead their students in discussing whether a somewhat ambiguous equation, such as $3 + 2 = 5 + 1 = 6$, was true or false. Instructions for selecting a video clip consistently specified the time limit and invited teachers to focus on what they noticed about their students' thinking but were otherwise fairly non-specific. Teachers shared and discussed video clips in a discussion board-like setting as shown in Figure 1.

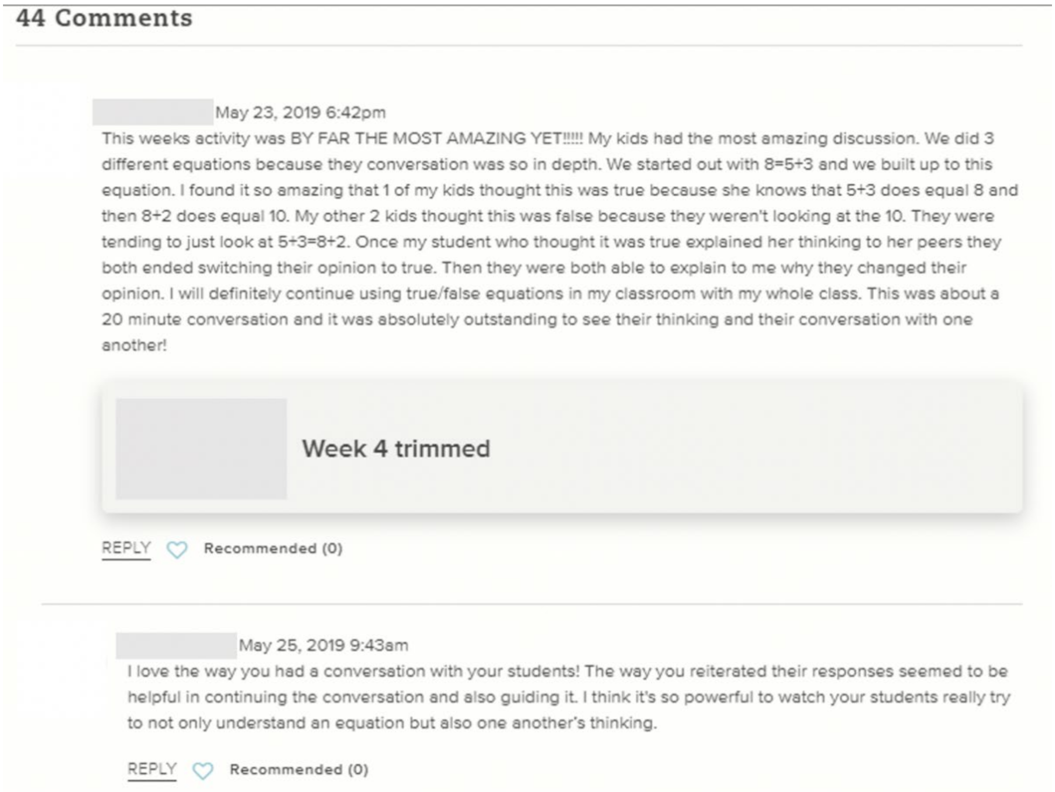

Figure 1. Example of selected video clip discussion.

Ten teachers from two well-resourced, predominantly white suburban school districts in the United States participated in the course in the spring of 2019, and we collected several sources of data to gain insight into participating teachers' selecting processes and associated reasoning. First, we conducted two short interviews with teachers just after they videotaped argumentation conversations in their classes, where we asked them how they anticipated selecting clips and whether there were any particular portions they would want to make sure to include. Second, we asked teachers to perform at least two think-alouds while selecting video clips, in which they were to describe what they were doing and thinking as they interacted with their recorded video and made selections. Third, we conducted a final end-of-course interview with each teacher, where we asked them to reflect on what they tended to select in their video clips and why.

In prior work with this data corpus, we engaged in systematic coding of teachers' considerations while selecting (Richards et al., 2021), which allowed us to survey, at a high level, the types of thinking observed. In that work, we noted the existence of aesthetic reasoning as one component of that thinking. Here, we extend our theoretical and analytical work with this construct, focusing on data assembled from five of the ten participating teachers who had a) complete selecting datasets and b) particularly rich think-alouds, the latter of which we felt provided unique insight into the varied aesthetic judgments teachers made about videotaped classroom events.

These five teachers had a mean of seven years of teaching experience (with a range from three years to 15 years); all identified as female and white, and one teacher identified as Hispanic or Latina. We describe more about how we approached the data after introducing key aspects of what we mean by aesthetics as a teacher thinking construct.

Aesthetics, the idea

We begin with an example drawn from an interview with a first-grade teacher, Allison (1), used to introduce the idea of aesthetic reasoning in prior work (Richards et al., 2021) and further unpacked here. This particular example is taken from our second interview with Allison, just after she filmed an argumentation discussion with her class and before she had selected a portion of the video to share online. During these interviews, we always asked whether a teacher had any initial thoughts about what parts of the recorded activity they might choose to share. When asked this question, Allison responded:

> So, I probably will leave out—usually I go for the ending because I feel like that's where like *the meatiest conversations* come from, but I feel like this one, the last [equation] I'll probably leave out and more skim towards like the middle to the beginning, and I feel like at the beginning the kids were more on track with like 3 + 5 = 5 + 3. (*emphasis added*)

Allison reported that typically she selects clips from the latter portions of activities since those portions are usually the "meatiest" (though that pattern did not hold in this particular instance). She did not elaborate on what she meant by "meaty," though one could infer a potential relation to where conversation was "more on track." The interviewer then asked her to say more about what she meant by "meaty."

> I: Mhmm. Yeah, and when you say meaty, like what do you—what counts as meaty?
>
> A: So, like the more in-depth conversations where they're like really able to explain their thinking, and then the opportunities where when it does make sense, and I have other kids like, "Can you repeat what so and so said"? Like those teachable moments.

Allison's noticing of "meaty" conversations is an example of the sort of *aesthetic judgments* that are our focus, and it has many features that typify these judgments. It is our intention to use the term *aesthetic* in a particular, technical sense—as a particular kind of knowledge system—that may be unfamiliar to some readers. In some loose respects, our usage does reflect everyday usages of the term; in other respects, it does not. Most fundamentally, our description of a system of knowledge as constituting an aesthetic is meant to describe features of the *form* of the knowledge—its structures and processes that act on those structures. In this respect, we closely follow the usage of the term proposed by diSessa (1993). In his account of the nature of intuitive physics knowledge and how it arises, diSessa provided a formal definition of a type of knowledge system that he called an *aesthetic*, explaining:

> The term is meant to be evocative of the functional characteristics of rich but structurally limited knowledge systems, which, notwithstanding their richness, appear fluid, data driven, and involve situation-specific reasoning (as opposed to plans and general methods) and idiosyncratic justification. (p. 187)

In diSessa's definition, an aesthetic is a knowledge system that consists of a collection of elements that are not highly organized. An aesthetic is activated and applied through a process of recognition, strongly driven by the data at hand. Further, since aesthetic judgments are undergirded by "structurally limited," less formalized knowledge systems and terminology, we should expect teachers to use variable ideas and language to express what they have in mind; in particular, we should expect them to draw on language that is somewhat specific to the situation currently under consideration.

Although diSessa's (1993) definition of an "aesthetic" is quite technical, it nonetheless aligns with some aspects of more everyday usages of the term. Consider, for example, the aesthetic judgments of wine connoisseurs. They might use words such as "complex" and "balanced" to describe a particular wine, with some consistency, and they would draw on a rich range of knowledge elements and experiences in doing so. Nonetheless, such judgments are simultaneously "fluid" and "data driven"; they are in-the-moment responses to particular sensory experiences. And a wine connoisseur might use varied language, perhaps cued by the particularities of a given wine, to explain what it means for a wine to be "complex."

We see the characteristics of an aesthetic reflected in Allison's judgments in the example above. Allison seemed to treat "meatiness" as something that could be recognized—perhaps relatively unproblematically, as she did not initially think to describe it further. However, when pressed, she applied a range of descriptors, suggesting that the bases of this judgment may involve a range of elements, some of which are more or less salient in particular situations. Indeed, although she used the word "meaty" throughout all of our interviews, the ways in which she unpacked this term varied. Here, for example, she described meaty conversations as "in-depth" and as "opportunities where when it does make sense." Across other data, depth was a relatively consistent descriptor associated with "meaty," but Allison also associated meaty with an "aha moment" (interview 1) and with being able to see diverse student thinking (final interview). These observations lead us to believe that for Allison, "meaty" is more than just a word—it reflects an aesthetic with some consistencies and complexities, and its application in particular situations may be nuanced and fluidly connected to a variety of considerations and inputs.

As emphasized above, diSessa's (1993) definition of an aesthetic is intended to be only structural. For him, an aesthetic is a system of weakly connected knowledge elements applied in a data-driven manner. But the aesthetic judgments in our own data do have some characteristics that are reminiscent of more everyday usages of the term. Though this was not always the case, the aesthetic judgments in our data were sometimes value-laden (as are those of a wine connoisseur). Here, for instance, Allison did not simply notice and characterize something that occurred; she positioned meaty conversations as desirable. Strictly speaking, in these interviews, teachers were responding to a question about which parts of a video were desirable for a particular purpose—the purpose of sharing in an online course with their colleagues. But, in actuality, their judgments often did not seem limited to this context; Allison's judgment that a portion of the discussion was meaty seemed to be naming an intrinsically positive attribute of that part of the conversation, regardless of the video-based task at hand.

It makes sense to us to think of the systems of knowledge that produce aesthetic judgments—systems that we call simply "aesthetics"—as part of the underlying machinery of teacher noticing. They produce readouts and evaluations that are, in a fundamental and important sense, "just seen" in classroom events. They become raw "noticed-things" (Sherin & Star, 2011) that are often treated as inputs to teacher reasoning and decision-making (e.g., Schoenfeld, 2008). Yet with respect to the noticing literature as described in the introduction, we note that an aesthetic seems to be a particular *kind* of noticed-thing that blurs distinctions between what teachers attend to and how they interpret or reason about objects of attention. For instance, noticing a "meaty conversation" embeds interpretations or evaluations within the noticed-thing itself. This contrasts with noticed-things that require little in the way of inferences, such as noticing that a particular student spoke in class today.

Aesthetics in teachers' video selecting work

As we looked across our data corpus of teachers' selecting processes, we noted a range of aesthetic judgments that teachers made with respect to what occurred in their classrooms. Briefly, the first and second authors independently identified all instances in the data corpus in which a teacher seemed to rapidly recognize and characterize a classroom occurrence, noting both what the teacher was naming (e.g., "meaty conversation") and descriptors or observations used by the teacher that may be part of the locally applied knowledge system. We then discussed and refined our collective understanding of each instance and discussed patterns and potential categories of aesthetics across the dataset. The first author then constructed analytic memos synthesizing instances into descriptive categories and examining prevalence across teachers.

Here, we elevate and characterize aesthetics that arose across multiple teachers. We do not put these forth as any kind of firm typology; rather, we frame these aesthetics as initial evidence-based characterizations that illustrate what an aesthetic (as a teacher thinking construct) may involve and sound like in practice, suggest varied domains for which teachers may have operational and potentially influential aesthetics, and form the basis for future work in this area. We also broadly acknowledge that focusing on aesthetic judgments is only one way of making sense of teachers' judgments that foregrounds their common structure and character; one could alternatively foreground other aspects of teachers' judgments, such as their epistemic underpinnings.

Student state-oriented aesthetics

We begin with a set of aesthetics that focused on different aspects of students' states—how students were participating, feeling, understanding, etc. As with most aesthetic judgments, these were often positioned as things one could "see" or "tell" directly from observational cues. Unlike some other aesthetic judgments, however, they at times incorporated language that suggested degree, in that students could demonstrate more or less of a given state.

We call one common student state-oriented aesthetic *engagement*, following from teachers' language. We believe that, even in everyday interactions, it is a common assumption that it is possible to tell when someone is "engaged" with us or with an activity—though it might be challenging to define what we mean or say why we think so. Four of the five teachers demonstrated evidence of judging whether and to what degree students were engaged in the classroom activity at different times in their video work, often via declarations without further explanation. For instance, a kindergarten teacher, Deb, described a week in which she filmed two argumentation activities and selected one to share in part based on her perception of students' engagement. She noted that "they were just so blah" (final interview) in relation to one of the activities, but they were highly engaged in the other: "I did this one just on a whim one day and I'm like, 'Oh, we need to stop and record this' because they got so into it" (final interview). Such judgments—of students collectively getting "so into it," or of other descriptors teachers used such as "more engaged," "so distracted," or "checked out"—likely involved complex, synthetic work across a range of sensory inputs, but they were framed as fairly direct read-offs of the data at hand. As first-grade teacher Allison noted, "You can kind of see like the engagement, you can see the kids who are kind of like zoned out" (interview 1).

Another emergent student state-oriented aesthetic across teachers was *understanding*—whether and to what degree students understood something or not. Here, teachers described whether students "realized" something, or were "confused" or "lost," often making such judgments based on observational cues (e.g., "they'll show if they're confused or they're not quite sure… just through their facial expressions" (Vicky, interview 1)). Again, these are complex judgments that are far from unproblematic; they require ascribing to students a cognitive state, based on their facial expressions, postures, tones of voice, etc. Furthermore, in the moment of teaching these judgments are not incidental; they are likely to have an impact on teachers' actions and interactions with students.

Contribution-oriented aesthetics

Teachers also made aesthetic judgments with respect to specific contributions from students. Here, the aesthetics were more explicitly valenced in nature, elevating and depicting particular contributions as "good" or "interesting" from the teacher's perspective. For instance, multiple teachers drew on a *good contribution* aesthetic, in which they demarcated particular contributions or segments of contributions with positive evaluative language: "She does a nice job using math vocabulary" (Dorothy, think-aloud 1); "This is where I got some really good observations" (Kendra, think-aloud 2); "That's a really important point" (Vicky, think-aloud 2); "I love that they were connecting across the subjects" (Deb, think-aloud 3). These sentiments were most common during selecting think-alouds, suggesting that they were activated for teachers in response to specific pieces of video data, and they at times shaped teachers' selections.

What we call the *interesting part* aesthetic was also a contribution-oriented aesthetic that teachers used to demarcate particular contributions, but these judgments had a different tenor. Here, teachers were reacting to contributions that intrigued them, sometimes because they were surprising or reflective of times when students posited ideas that teachers had not contemplated or showcased abilities that teachers had not expected. This aesthetic was distributed across data sources, suggesting that teachers identified parts that were interesting to them during their interactions with students while capturing video, as well as while selecting portions to share. Further, while teachers on occasion simply cited something as "interesting," they tended to also name *what* was interesting, and at times *why.* They added this specificity more often with the *interesting part* aesthetic than with others. For instance, a kindergarten teacher, Dorothy, described a line of thinking she found "interesting": "He wanted it to look like 2 + 5 = 2 + 5 [rather than 2 + 5 = 5 + 2] and then it would be true, and then at the end he realized that it still is the same, which I think is- it's interesting" (think-aloud 2). At the end of the course, Dorothy noted that she made selections partly based on parts that she "found really interesting or different or that were surprising" (final interview). When pressed to unpack what "interesting comments" meant, Dorothy replied:

> I kind of had in my mind, things that they were going to say, and things that they would notice, and sometimes they said something completely different that I was like "Wow, I didn't even think of that," so I thought that was awesome… Things that surprised me that I didn't really think they could do, or that I didn't think they would notice (final interview).

Other teachers also depicted students' approaches or understandings as "interesting," "fascinating," or "compelling" and made sure they were included in their selections (e.g., "I think it's so fascinating that she's- when she talked about flipping it around. She's just doing it completely backwards… okay, so I'm keeping that" (Vicky, think-aloud 2)). In another example, kindergarten teacher Deb noted how a "whole video" in which her class discussed an equation with variables was "very fascinating. I just thought it was so interesting talking about variables with kindergartners" (think-aloud 3). Deb reiterated her interest in this particular discussion and how it influenced her selections several times throughout her final interview:

> I was just like so intrigued by their understanding… there were times when I trimmed the video more on something that I just found really like compelling that a student had said… I'm remembering it was something [student] said… where she shocked me in understanding what "a" could stand for… their thinking on that one was just so fascinating to me (final interview).

Here, Deb used varied language—"intrigued," "compelling," "shocked," and "fascinating"—to depict the part she found interesting and specified that while the "whole video" was fascinating, she was most tuned into a particular student's understanding of how to work with a variable that she found surprising.

Interaction-oriented aesthetic: Good conversation

A third category of aesthetic that arose across multiple teachers focused on the nature of interactions among students. In our course context, three of the five teachers drew on what we call a *good conversation* aesthetic, which had several characteristics. First, it was often used as a descriptor without much further specification—teachers noted where the conversation was "good," "better," or "best," often positioned in contrast to where the conversation was "slow" or "not argumentative" (given the content of the course). Contrasting "good conversation" with what teachers deemed to be less good conversation seemed unique to this aesthetic.

Second, when teachers did specify what made a conversation "good," they focused on specific ways that students interacted with each other. For instance, Dorothy described that students "were actually listening to each other," in contrast to portions where she perceived that "once one kid was talking, the other two were not listening at all" (interview 1; note here that this aesthetic also seems tied to the *engagement* aesthetic in Dorothy's judgment of when students were listening). Other teachers noted that "good conversation" was where "there was kind of a back and forth between other students" (Kendra, final interview) or where students explicitly disagreed with each other (Vicky, final interview).

Story-oriented aesthetic: Completeness

Finally, four of the five teachers demonstrated aesthetic judgments that seemed to be more about the holistic nature of the classroom event or video clip, judgments that we link to a *completeness* aesthetic. Here, teachers considered and judged whether a given event or clip seemed to reflect a "complete" or "whole" story.

Take the following think-aloud example from Kendra, a second-grade teacher, who had filmed her students' discussion of whether two pairs of images were the same or different and was considering what to include in her selected clip. She watched how students discussed both pairs of images and noted that in one discussion, a particular student took over and "it wasn't really, um, argumentative" (the *good conversation* aesthetic). She noted, "I'm just gonna eliminate the second conversation and, um, my video will now capture the complete conversation on our first same or different… picture" (think-aloud 5). Note here that while the *good conversation* aesthetic seemed to drive which conversation to include, Kendra also made a *completeness* judgment—that the video would "capture the complete conversation" she selected.

Kendra returned to this *completeness* aesthetic on multiple occasions. She sought to reflect "the conversation as a whole" (think-aloud 3), and this consistently led her to trim at what she deemed to be natural boundaries, such as after a spot where a student was "finishing a thought" (think-aloud 4). Other teachers drew on similar judgments of what made something complete. For example, Allison explained, "if I could include the whole part of the last person talking I would, but always that beginning part I felt like it was important to like capture the whole conversation" (final interview). Similarly, Deb made sure to "get to the end of [the student's] thought" (think-aloud 1) before trimming. While there were some commonalities in what made an event or a clip feel complete, such as starting and stopping at natural boundaries in talk or tasks, these judgments were also situation-specific in that what felt "complete" to a teacher for one argumentation activity did not always match what felt complete for another activity. Returning to Kendra's examples, what felt "complete" in the same or different discussion described above was showing the entirety of students' discussion of one pair of images; what felt "complete" in another argumentation activity in which students discussed what would make particular equations true (e.g., 1 x __ = 2 x __) was showing portions of how students discussed two equations back-to-back, to be able to showcase the whole trajectory of their reasoning.

Discussion

This paper is our first extended attempt to articulate our ideas concerning what we believe to be an underexplored component of teacher noticing and thinking—teachers' aesthetic judgments. To recap, these are rapid, at times value-laden judgments that we saw teachers make about, and in response to, classroom events. Drawing on diSessa's (1993) notion of an aesthetic as a rich but loosely organized knowledge system, we argued that aesthetics that are "just seen" by teachers are likely to be an important part of teacher noticing. Specifically, they reflect what teachers intuitively notice in classroom events in a way that seems to merge attention and interpretation, blurring dimensions often treated as separable in studies of noticing.

With respect to teacher learning and learning to notice in particular, we believe that the prevalence and ease with which teachers made aesthetic judgments while selecting video clips in our course context suggest that such judgments are likely at play for teachers even if they are not made explicit through professional development activities. Furthermore, we believe aesthetic judgments can reflect substantial professional expertise. Indeed, precisely because an aesthetic is a largely informal kind of knowledge system, we anticipate that aesthetics may be largely built up from experiences observing and leading classrooms, in addition to other sources of knowledge. Teachers' aesthetic judgments likely constitute some of the raw "noticed-things" (Sherin & Star, 2011) that can be built on, and/or critically investigated with respect to how relational positionalities and lived experiences shape noticing, in professional development contexts.

However, we are aware that much work remains to be done to more fully investigate and articulate the idea and its implications. We conclude here with a discussion of what we see as the most pressing empirical and theoretical issues. First, from an empirical point of view, an important next step is to investigate teachers' aesthetics in contexts beyond video selection. In some respects, teachers' video selection processes provided an ideal context within which to see aesthetics, as they involved teachers judging segments of classroom activity and choosing some segments over others. But again, our argument for the importance of aesthetics hinges on our belief that they are also active throughout other teaching activities. We believe there is a strong prima facie case to be made that aesthetic judgments play an important role when teachers, for example, lead a classroom discussion. Even fine-grained models of teacher decision making, such as the one developed in Schoenfeld (2008), include what are essentially black boxes in which teachers must make complex and important judgments, such as whether a particular student question is generative to pursue or reflective of a broader lack of understanding in the class. Thus, one concrete next step is to study how and when aesthetic judgments are made across multiple teaching activities, including within situated classroom events.

Another contextual consideration has to do with the specific focus of the course as related to the specific aesthetics activated among teachers. For example, the fact that teachers were to engender and capture student "argumentation" likely provoked a focus on interaction-oriented aesthetics, in which teachers judged whether and how students interacted with each other's contributions. Similarly, the prevalence of story-oriented aesthetics in our data corpus was likely dependent on the particular context of selecting video clips that would be comprehensible to share with peers (though we believe that a focus on discussion features such as "closure" is likely not unique to this context). Further work could explore which kinds of aesthetics are commonly activated in which kinds of contexts, as well as potential patterns across contexts and relations among aesthetics in action. For instance, we noted above how judgments of the quality of a discussion might be linked to judgments of engagement. We anticipate, as we expand the study of teacher aesthetics across contexts, that we will find aesthetics that tend to be employed together, and in characteristic ways.

A different empirical question concerns the degree to which there is individual and/or cultural variability in teachers' aesthetics and their use. On the one hand, multiple teachers in this study's context showed some focus on student engagement and the quality of student ideas. However, there was also a great deal of fine-grained texture to these judgments. Just as a wine connoisseur might employ a rich vocabulary of terminology to describe the flavor of wines, so did teachers use varied language to talk about the flavor of student ideas and student conversation. Future research could examine commonalities and variations in readouts and language across teachers and instructional contexts.

There also remain a variety of questions about teachers' aesthetics and aesthetic judgments that are more theoretical in nature. As a novel construct with respect to teacher thinking, the definition and posited characteristics of teachers' aesthetics will benefit from ongoing refinement in relation to additional teacher thinking constructs, related interdisciplinary perspectives, and other examples of aesthetic judgments among teachers. As with many constructs, we anticipate that refinement of the construct itself and associated heuristics for identifying aesthetics in data will co-evolve. Further, understanding teachers' complex judgments of classroom events through the lens of aesthetics is only one way of exploring what is happening—a way that affords attention to the structure of the judgments. Additional work in this area may help to clarify how the structure of aesthetic judgments relates to other interpretive lenses that instead focus more directly on content or context. There is also work to do concerning the relationships that may exist among aesthetics. For example, can they be nested one inside the other, similar to schemata (e.g., Rumelhart, 1980)? When considering an aesthetic, such as the *interesting part* aesthetic described above, in what ways does it make sense to conceptualize its counterfactual (i.e., a part that is not very interesting) as *part of* the aesthetic versus its own aesthetic? Finally, there are also dimensions of variability across aesthetics that deserve attention. For example, some aesthetic judgments seem to be more tacit than others, and some seem to have a stronger valence. We hope that the existence of these questions is suggestive that this is a worthwhile area for further research.

Computational Thinking Unplugged for Science: Unplugged CT Professional Development for Inservice Science Teachers

Vance Kite, North Carolina State University, vkite@ncsu.edu
Soonhye Park, North Carolina State University, spark26@ncsu.edu

Abstract: Computational thinking (CT) is a fundamental skill for 21st Century work. Historically, CT instruction has existed primarily in computer science courses that lack both racial/ethnic and gender diversity. Scholars argue for broadening CT access for K-12 students by integrating CT in core curricula, however, CT/content integration remains uncommon. A major barrier to widespread CT integration is limited CT professional development (CT-PD). Given that, we drew on teacher professional development research to design and implement a fully unplugged CT-PD with inservice secondary science teachers that focused on unplugged strategies for integrating CT in core science curricula. We examined the influence of the CT-PD on teachers' CT understanding and CT integration self-efficacy, as well as, program components that participants identified as particularly beneficial to their CT understanding and self-efficacy in CT/science integration. This study provides important insights for the development of future CT-PD offerings for inservice teachers.

Keywords: computational thinking, CT unplugged, science education, teacher professional development

Introduction

Many scholars assert that computational thinking (CT) is a fundamental component of preparing students for the complex future of work, and that all students must have opportunities to build proficiency with these practices during their K-12 education (Grover & Pea, 2018; Ketelhut et al., 2020). Unfortunately, opportunities to engage with CT practices have, historically, been confined to elective computer science courses which lack racial, ethnic, and gender diversity (Gallup Inc. & Google Inc. 2016). Integrating CT into core curriculum is the most promising strategy for exposing diverse groups of learners to these critical practices (e.g., Grover & Pea, 2018; Yadav et al., 2016). While efforts to integrate CT with subject-area curriculum have been ongoing for more than a decade, CT/content integration (CTCI) is not yet commonplace; Shute and colleagues (2017) identify a lack of consensus about the framing of CT and few research-supported best practices for CTCI as a potential reason. Other scholars point to challenges that include teachers' concerns about access to and proficiency with technology (Israel et al., 2015), teachers' low levels of CT understanding (Kite et al., 2020), teachers' low CT self-efficacy (Bower et al., 2017), and limited CT professional development (CT-PD) support for inservice teachers (Sands et al., 2018).

Low levels of teacher CT understanding and self-efficacy in CT/science integration are particularly concerning because teachers are unlikely to integrate CT with their existing curriculum if they lack either sufficient understanding of CT or confidence in their ability to create quality CT learning experiences for their students (Ketelhut et al., 2020). Bower and colleagues (2017) demonstrated that teachers' CT understanding and self-efficacy can be enhanced by short-term, high-quality PD opportunities, however, Ketelhut et al. (2020) and Sands et al. (2018) both note that much CT-PD work has focused on preservice teachers and that research on CT-PD experiences for inservice teachers is in its infancy. Additionally, given the relative newness of CT-PD research, the community is still working to identify highly-effective components of CT-PD interventions. Nonetheless, ensuring that all students engage with CT practices in their K-12 STEM classrooms depends upon adequately-trained teachers who understand CT and feel confident in infusing it into their curriculum (Yadav et al., 2017).

Bearing in mind technology-related barriers to CT integration and the need for CTCI, we designed, implemented, and examined a week-long CT-PD called Computational Thinking Unplugged for Science (CTUPS), which focused on non-technological (Unplugged) approaches to integrating CT with secondary science content. This proposal presents an overview of CTUPS and its theoretical underpinnings, and reports its influence on teachers' CT understanding and self-efficacy in CT/science integration, as well as, components of CTUPS that teachers identified as uniquely beneficial. Our work was guided by the following research questions: (1) What is the effect of the CTUPS program on inservice secondary science teachers' CT understanding and self-efficacy in CT/science integration? (2) What elements of CTUPS do participants identify as most impactful on their CT understanding and self-efficacy in CT/science integration?

Theoretical background

The design of CTUPS is based on three lines of scholarship in the fields of CT, computer science (CS), and teacher education. First, in the decade since Jeanette Wing (2006) first described her conceptualization of the practices that comprise CT, many groups have forwarded definitions and frameworks for CT without reaching consensus (Grover et al., 2020). Lacking a common understanding, we adopt Fraillon et al. 's (2019) definition of CT (Table 1) as the conceptual foundation of our work because we believe it provides a vision of CT that can be operationalized in K-12 science classrooms. Specifically, Fraillon and colleagues' description of two distinct phases of CT (Conceptualizing problems and Operationalizing solutions) provides a useful framework for walking teachers and students through the process of developing an algorithmic solution to a complex problem.

Table 1: The 2018 ICILS computational thinking assessment framework (Adapted from Fraillon et al., 2019)

Strand	Aspect
Conceptualizing problems	Knowing about and understanding digital systems. Formulating and analyzing problems. Collecting and representing relevant data.
Operationalizing solutions	Planning and evaluating solutions. Developing algorithms, programs, and interfaces.
Definition	*Computational thinking refers to an individual's ability to recognize aspects of real-world problems which are appropriate for computational formulation and to evaluate and develop algorithmic solutions to those problems so that the solutions could be operationalized with a computer (pg. 27).*

Second, computer programming is the dominant tool of CT education (Kite et al., 2018; Moreno-León et al., 2018). However, multiple scholars identify restricted access to technology, teacher discomfort with technology, and teachers' lack of programming experience as barriers to CT/content integration (Kite et al., accepted; Bower et al., 2017; Israel et al., 2015). As an alternative to technology-focused CT practices, Lu & Fletcher (2009) and Caeli and Yadav (2020) argue that students and teachers could benefit from an unplugged-first approach that builds foundational CT skills. In 1998, Bell and colleagues published the first CSUnplugged collection of games and puzzles for teaching CS concepts without a computer. Over time, the term "Unplugged" has expanded to encompass any CT or CS activity that does not use technology. Though Peel et al., (2019) demonstrated the potential for unplugged approaches to fusing CT with science curricula, Moreno-León and colleagues (2018) highlight the lack of research in this arena. Given that, to address tech-related barriers, and in response to the need for research on unplugged strategies for integrating CT in disciplinary content, we adopted a fully-unplugged approach to the implementation of CTUPS.

Lastly, the design of CTUPS was guided by Darling-Hammond et al.'s (2017) and Desimone's (2009) frameworks for effective teacher PD. Drawing on the work of these scholars, we designed the main features and activities of CTUPS around the following essential elements of effective PD: 1) A focus on subject-area content. 2) Active learning strategies. 3) Opportunities for collaboration between teachers in similar grades/content areas. 4) Thirty contact hours. 5) Coherence with both teachers' existing beliefs about teaching and school/district policies. 6) Modeling of effective teaching practices by facilitators. 7) Time for teachers to reflect on what they have learned and to receive feedback on products and implementations. Consequently, each day followed an experience, collaborate, plan, reflect structure.

Methods

This study employs mixed methods to collect, analyze, and interpret both quantitative and qualitative data to answer the research questions.

Overview of the Computational Thinking Unplugged for Science (CTUPS) program

CTUPS is a weeklong CT-PD for secondary science teachers that focuses on unplugged strategies for integrating CT practices into existing science curriculum. This CT-PD operationalizes the Fraillon et al. (2019) framework as a structure for moving teachers through the unplugged process of developing an algorithmic solution to a complex problem; in this case, human disturbance of an ecosystem. Each day of the program was split into two halves; experience and plan. In the morning, teachers acted as students to engage in activities that led them through the process of, first, identifying a human disturbance to an ecosystem, then, developing an unplugged algorithmic solution to the disturbance (Table 2).

Table 2: CTUPS activities that allowed teachers to experience CT-infused science learning

CT Practice	CTUPS Activities
Day 1: Systems Thinking	Teachers selected an ecosystem and associated human disturbance; identified system inputs, outputs, and emergent phenomena; created a concept map to visualize relationships in the ecosystem; and defined boundaries of the system and rules that govern its operation.
Day 2: Problem Decomposition	Teachers selected a human disturbance that functions as a system input (e.g., Fertilizer runoff in waterways), identified its associated output (e.g., Eutrophication), and used a "5 Whys" protocol to decompose the root causes of the human activity.
Day 3: Data Practices	Teachers identified multiple sources of data that could be used to understand the problem, developed strategies for obtaining the data, and created sample tables and visualizations that could be used to organize and display the gathered data.
Day 4: Algorithm Creation	Teachers brainstormed a list of possible elements of a solution to their problem, then organized the elements into an algorithm for solving the problem. Algorithms were required to included loops and conditional statements.
Day 5: Abstraction	Teacher teams were paired to combine their individual algorithms into a single, more general algorithm that could be used to address both teams' problems.

In the afternoon, teachers translated their experiences into adaptations of their existing science curriculum. Table 3 provides an overview of the key features of CTUPS and their alignment with the features of effective professional development as described by Darling-Hammond et al. (2017) and Desimone (2009).

Table 3: Key features of CTUPS and their alignment with the elements of effective teacher PD

Element	Description	CTUPS
Content Focused	A focus on subject knowledge and associated pedagogical knowledge.	Teachers engage in CT practices in the context of subject matter that they will teach (i.e., human disturbance of ecosystems). Teachers are provided time to align CT practices with their content standards and write curriculum. Each day of CTUPS is devoted to building CT understanding and efficacy by engaging in unplugged practices that focus on one of the CT aspects described by Fraillon et al. (2019).
Active Learning	Engaging in the process of constructing knowledge rather than passively receiving knowledge through lectures.	Teachers participate as learners in unplugged CT-infused science activities. All knowledge dissemination occurs via collaborative groupwork protocols (i.e., no lecture).
Collaboration	Providing opportunities for teachers to share knowledge while engaged in learning and writing curriculum.	All learning activities occur in teams. Curriculum alignment and lesson planning occurs in teams. Teams provide one another with feedback on curriculum products.
Collective Participation	Collective participation from teachers in the same school, grade, or district.	Teachers placed in teams of 2-3 based on their grade level, subject area, and district.
Sustained Duration	Twenty or more contact hours.	CTUPS consists of 30 contact hours over 5 days.
Coherence	Coherence to curriculum, student needs, teacher knowledge and beliefs, and school, district, and state reforms and policy.	Teachers are teamed based on grade level and district to allow teachers to write curriculum that aligns with both state standards and district reforms and policies.

Modeling	Facilitators model effective pedagogical strategies.	The facilitator models effective instructional practices while implementing "student" activities.
Feedback and Reflection	Participants receive peer and facilitator feedback on work products and are given opportunities to reflect on their learning.	Teachers keep a reflection journal where they are asked to respond to daily prompts that encourage them to reflect on the day's activities, curriculum alignment, implementation barriers, and the state of their own knowledge and confidence.

Participants
Eleven secondary science teachers in a Southeastern state in the U.S. participated in CTUPS. Their demographics are provided in Table 4.

Table 4: Demographic characteristics of CTUPS participants ($N = 11$)

	n (%)		*n (%)*
Male	1 (9)	Teaching Experience	
Female	10 (91)	3-5 Years	4 (36)
Race/Ethnicity		6-15 Years	3 (28)
African American	4 (36)	20 or More Years	4 (36)
Asian	1 (9)	Middle School	6 (55)
White	6 (55)	High School	5 (45)
		Low Income (Title 1) School	6 (55)

Data sources
Data sources for this study include pre, post-, and three-month-delayed-post surveys investigating qualitative and quantitative CT understanding (Sands et al., 2018) and a modified Computer Technology Integration Survey (Wang et al., 2004), as well as, daily "exit tickets" and reflection journals completed during the program, and an end-of-program evaluation questionnaire. All quantitative items on the CT understanding and self-efficacy instruments were 5-point Likert items with 1 representing low levels of understanding/self-efficacy and 5 representing high levels. Teachers' qualitative understanding of CT was investigated via two open ended questions on the pre, post, and delayed-post surveys that asked teachers to define CT and describe the role of CT in science learning. Daily "exit tickets" asked teachers to record three things they learned, two comments, and one question on a Post-it. Reflection journals asked teachers to reflect daily on two to three prompts relating to their CT understanding and thoughts pertaining to integrating CT in their science classrooms.

Data analysis
Quantitative data analysis was conducted using descriptive statistics and paired-sample t tests to identify differences between teachers' pre/post, and delayed-post scores on measures of CT understanding and self-efficacy and Cohen's d was used to calculate the direction and magnitude of the effect of the PD. To provide richer insights into the development of teachers' CT understanding and CTCI self-efficacy, as well as particularly beneficial program elements, triangulation of multiple data sources (Patton, 1999) and the constant comparative method (Corbin & Strauss, 2015) were used to qualitatively analyze teachers' written artifacts. Specifically, all qualitative data was, first, open-coded to capture the essence of each quotation, with quotations expressing similar sentiments given the same code. Axial coding was then used to identify trends in the data by aggregating open codes into categories. Finally, common themes in teachers' responses emerged through the process of selective coding. To check the reliability of the coding scheme, 25% of the data was randomly selected for coding by a second coder; an intercoder agreement level of 90% and Krippendorff's alpha of 0.98 were calculated. Additionally, to understand the alignment of participants' understanding of CT with that of the broader CT community, we classified teachers' CT definitions into two categories: basic and informed. Using the work of Weintrop and colleagues (2016) as a guide, teachers' definitions of CT or descriptions of CT that include the following (or similar) practices were identified as informed: (1) Using computers to solve complex problems, (2) Structured problem solving, (3) Data creation, analysis, and visualization, (4) Systems thinking, and (5) Creating or using models or simulations. Readers will see the codes *Canonical definition* and *PRADA* (Pattern Recognition, Abstraction, Decomposition, Algorithms) *to solve problems* referenced. A *Canonical definition* of CT includes using a specific CT practice and technology to solve problems. *PRADA to solve problems* includes a specific CT practice and problem solving but does not include the use of technology.

Results

Effects of CTUPS on Participants' CT Understanding and CTCI Self-efficacy

Quantitative analysis of teachers' pre, post, and 3-month-delayed-post surveys of CT understanding and integration self-efficacy reveal that CTUPS significantly enhanced participants' understanding of CT and CTCI self-efficacy. As shown in Table 5, teachers' mean CT understanding improved by 0.983 points (on a five-point scale) at the conclusion of CTUPS. Three months after the program, their understanding remained elevated by 0.739 points. Paired-sample t tests indicate that the change measured at each milestone was significant (t (10) = 5.567, t (9) = 4.792, p < .001) and Cohen's d values of 1.866 and 1.515 reveal a large effect on teachers' understanding. Regarding teachers' feelings of CTCI self-efficacy, following CTUPS, teachers' mean self-efficacy score improved by 1.976 points (on a five-point scale); enhanced self-efficacy persisted three months after the program (Δ = 1.646). Paired-sample t tests reveal the significance of the changes at both times (t (10) = 6.741, t (9) = 7.689, p < .001) and Cohen's d reveals large effect sizes of 1.866 and 1.980, respectively.

Table 5: Effects of the CTUPS program on secondary science teachers' CT understanding and CT integration self-efficacy

	Mean	Standard Deviation	Change	Cohen's *d*
Pre-Understanding (n = 11)	2.983	0.294		
Post-Understanding (n = 11)	3.965	0.508	0.983	1.866
Delayed-Post-Understanding (n = 10)	3.721	0.586	0.739	1.515
Pre-Efficacy (n = 11)	1.987	0.957		
Post-Efficacy (n = 11)	3.963	0.507	1.976	2.033
Delayed-Post-Efficacy (n = 10)	3.633	0.684	1.646	2.432

Qualitative analysis of changes in teachers' CT understanding

Qualitative analysis of teachers' definitions of CT as provided on the three surveys and in their reflection journals reveal a rapid and durable shift in teachers' conceptualization of CT. Table 6 presents changes in the proportion of teachers' definitions that were assigned to five categories that emerged from our qualitative analysis.

Table 6: Qualitative changes in teachers' definitions of CT

Category	Pre *n* (%)	End Day 1 *n* (%)	Post *n* (%)	Delayed Post *n* (%)
Solving problems with computers or specific CT practices	5 (29)	12 (75)	10 (91)	9 (82)
Related to math or data	5 (29)	4 (25)	1 (9)	1 (9)
Generic problem solving	3 (18)	0 (0)	0 (0)	1 (9)
A specific type of thinking	2 (12)	0 (0)	0 (0)	0 (0)
Other	2 (12)	0 (0)	0 (0)	0 (0)

Prior to the beginning of the CTUPS program, the majority of teachers' definitions (59%) revealed basic understandings of CT. While several initial definitions were identified as informed, these definitions only referenced single CT practices (e.g. Pattern Recognition) and none of the teachers provided what would be considered to be a complete, *Canonical definition* of CT. Further, teachers frequently qualified their pre-survey definitions with phrases like "*I think*" or "*I imagine.*" At the end of the first day of the program, teachers were again asked to define CT. In contrast to their definitions at the beginning of the day, this set of definitions shows that 75% of the teachers provided informed understandings of CT, and three teachers gave full, *Canonical definitions* of CT. For example, one teacher stated that CT is "*A problem solving method using data to find patterns in order to create algorithms to solve a problem.*" Of the 11 definitions of CT provided on the post-survey, 91% were labeled informed and four teachers provided *Canonical definitions* of CT. The number of open codes used to analyze teachers' definitions decreased from 12 on the pre-survey to four on the day five post-survey; indicating that over the course of the five-day program, teachers' understandings of CT refined and coalesced around academically-accepted CT conceptualizations. Three months after the conclusion of CTUPS, teachers were, again, asked to define CT. Eighty-two percent of teachers' responses were identified as informed. As with the immediate-post-survey results, teachers' responses on this survey most frequently described CT as *PRADA to solve problems.* For example, one teacher defined CT as "*A process for conceptualizing problems and designing solution algorithms.*" Unsurprisingly, we do note some degradation in teachers' understanding of CT over the intervening three months between the conclusion of CTUPS and the delayed-post survey, and hypothesize that the decay stems from a lack of ongoing professional support.

Qualitative analysis of changes in teachers' CT integration self-efficacy

Sixty-one quotations gleaned from teachers' exit tickets and daily reflection journals were open-coded and categorized according to whether they demonstrated *Low efficacy, Growing efficacy,* or *High efficacy.* Considering the proportion of quotations housed in each of these categories for each of the days reveals that teachers' perceptions of their CTCI self-efficacy steadily improved over the course of the CTUPS initiative (Figure 1). Characteristic of statements written at the end of the first day were remarks such as "*This broad concept makes me uncomfortable*" and "*I feel much more prepared for the rest of the week.*" By the end of the second day, teachers' hinted at their growing efficacy through statements in the vein of "*CT is becoming clearer and clearer now.*" By the third and fourth days of the program teachers' efficacy had undergone a significant transition. Their writings from these two days are replete with statements like "*I am seeing ways to integrate CT in already created materials that middle schoolers can use and understand*" and "*I am a believer in CT!!! I cannot wait to use it in my classroom.*" One teachers' remark in her reflection journal from the first day may provide some insight into why teachers' self-efficacy changed over the course of the program. On day one, this teacher stated that "*I am starting to see that it is more of me starting to feel comfortable so that my students will be able to benefit from me introducing CT into my lessons.*" Other similar statements sprinkled across the four days indicate that teachers' felt that they, first, needed to become comfortable with CT before they had confidence that they could bring CT to their students. We hypothesize that presenting CT as a process and focusing on one Fraillon et al. (2019) practice each day may have allowed teachers to progressively build their understanding and comfort as we moved through the process of understanding a problem and developing a solution.

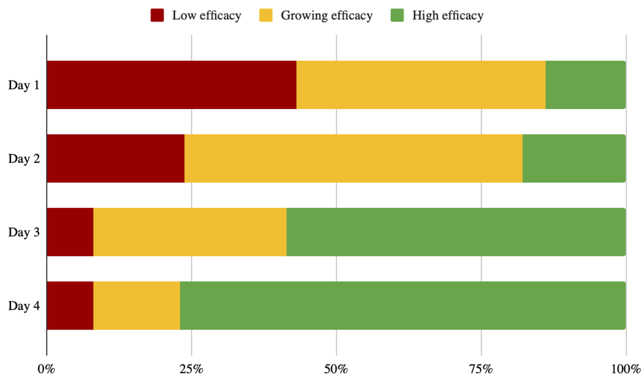

Figure 1. Change in teachers' statements of CT integration

Key elements of the CTUPS program

Qualitative analysis of 76 quotations gleaned from teachers' "exit tickets" and post-surveys resulted in 34 codes that were organized into four categories; three identifying particularly beneficial program elements and one identifying an element that should be changed. Thirty-one of the teachers' quotations about elements of CTUPS that they believed enhanced their CT understanding and CT integration self-efficacy fell under the theme *Practicing CT in the context of my content.* Within this theme, there were three categories of quotations, *CT-specific activities, Working through the process,* and *Contextualized practice.* In particular, teachers called out *Working through the process* and *Creating algorithms* as the most specific elements that enhanced their understanding and efficacy. The following quotation captures both of these sentiments "*The first three activities* [concept mapping, problem decomposition, data identification] *most impacted my understanding of CT because my thinking had to be restructured before getting to the algorithm.*"

In addition to practicing CT in the context of their curriculum, 22 of the teachers' quotations focused on the value they found in *Dialoging and collaborating with other teachers.* Teachers' writing across the documents are filled with statements that reflect the value that they found in working through the process of learning CT and developing CT-infused curricula with a group of like-minded teachers. One teacher noted that "*The true gift of our week this summer was having two other 8th grade science teachers to collaborate with. We all knew our standards, and were able to share our current labs, projects, and assignments. Integrating computational thinking in our curriculum was a natural next step.*" Along with collaborating with teachers in similar teaching circumstances, teachers emphasized the benefits that they found in the group debrief sessions that took place following each of the model CT activities and the peer feedback that they received on curriculum products developed throughout the program. In addition to the two above-mentioned themes, teachers also identified the *Program progress*, *Good model teaching,* and *Time to plan* as beneficial elements of CTUPS. Finally, with regards to program improvement, 11 of the teachers' quotations centered on the theme of *Beginning with a preview of the process and product.* The CTUPS program was designed using an explicitly constructivist approach, whereby teachers constructed their knowledge of CT by working through the practices of CT identified by Fraillon et al. (2019) as a process for producing an algorithm to solve a manmade environmental problem. The act of creating the algorithm was the culmination of the process and did not occur until day four. As a result of the constructivist design, participants were not provided with a vision of the final product (an algorithm) at the beginning of the program. While there was one teacher that appreciated this approach, most comments were in the vein of "*Do the algorithm as early as Tuesday so teachers will have more chance to digest what they needed to do at the end.*"

Discussion and implications

The results of this study point to the potential of fully-unplugged CT-PD programs for building inservice science teachers' CT understanding and CTCI self-efficacy, while providing them with CTCI strategies and addressing tech-centric CT concerns. Accordingly, we offer three implications for CT researchers and educators. First, our work, along with the work of Peel et al. (2019), demonstrates that unplugged CT activities like systems mapping, problem decomposition through tree maps, planning for data collection and analysis/visualization, and creating unplugged algorithms can effectively build teachers' and students' CT proficiency while supporting science content learning and practice as outlined in the Next Generation Science Standards (NGSS) (NGSS Lead States, 2013). Though some (e.g. Denning, 2017) will argue that CT education must include programming, we contend that programs like CTUPS can provide teachers with rich experiences that provide foundational CT understandings upon which later coding-centric CT instruction can build (Caeli & Yadav, 2020). Given that our program is a first attempt at a fully-unplugged approach to integrating multiple CT practices in science curricula, further research is needed to identify best practices for the design and delivery of unplugged CT-PD and to compare the affordances of unplugged CT-PD to its plugged counterparts with regards to CT/science integration.

Second, in line with the work of other teacher PD scholars (e.g. Darling-Hammond et al., 2017; Desimone, 2009), the results of our study demonstrate the importance of engaging teachers in learning experiences that they find to be relevant, applicable, and meaningful to them. In the case of CTUPS, involving teams of teachers in the collaborative task of using CT practices to produce a solution to an environmental problem was central to both building teachers' CT understanding and increasing their CTCI self-efficacy. The value that CTUPS participants found in practicing CT in context and collaborating with other teachers underscores the work of Ketlehut et al. (2020) and Sands et al. (2018), which both discuss the need for CT-PD partnerships whereby teachers provide subject-area and pedagogical knowledge and CT-PD providers provide CT content and learning experiences. Recognizing and leveraging teachers' expertise would appear to be emerging as a best-practice for future CT-PD offerings. Additionally, our findings accord with the work of others in demonstrating that CT-PD should be contextualized in teachers' discipline/curriculum (Yadav et al., 2017) and include time for teachers to identify CT/curriculum alignment and to write lessons for their classrooms (Ketelhut et al., 2020).

Finally, our work demonstrates the potential of operationalizing the Fraillon et al. (2019) CT framework as a guide for moving teachers and students through the process of developing computational solutions to complex problems. As far as the authors are aware, the CT education community has not previously presented individual CT practices connected as a coherent and systematic problem-solving process. This study, however, indicates that progressively moving teachers through the process of (1) understanding and mapping a natural system, (2) identifying and decomposing a problem, (3) identifying potential data sources and visualizations, and (4) creating an unplugged algorithmic solution, effectively scaffolded progressive construction of teachers' CT understanding. Further research on the affordances of operationalizing this framework as a process may illuminate the benefits of teaching CT as a coherent and interconnected set of practices for solving complex problems.

Turn-usurping in dialogic collaborative problem solving

Liru Hu, The University of Hong Kong, liruhu.hku@gmail.com

Abstract: Dialogic collaborative problem solving (D-CPS) emphasizes the equal rights of group members. Turn-usurping is one approach of turn-taking where a student usurps the floor which has been offered to another person by the last speaker. It reflects speaker's strong agency in seeking for participation opportunities and hasn't been fully explored in literature. The present explorative study adopted a mixed-method approach to examine major features and functions of turn-usurping in D-CPS. Participants were 168 primary school students who were assigned into 42 four-person groups to solve three open-process mathematical problems. Results showed that turn usurpers tended to have low intellectual status, low confidence in mathematics and high social anxiety. Turn-usurping had positive impact on maintaining participation equity and moving forward and complexifying group discussions. The findings suggested that it is practically meaningful to promote an equitable interaction environment where each member is encouraged to freely jump in.

Introduction

Following the epistemological assumptions of Bakhtin's dialogism (1929/1984), the present study defines dialogic collaborative problem solving (D-CPS) as a complex dynamic process whereby two or more consciousnesses, with equal rights and each with its own world, combine but are not merged in the unity of solving a shared problem. Students' verbal engagement is an essential end in D-CPS. Joint solutions emerge from and only exist in the dialogue whereby group members open themselves to each other's voices and augment their own.

Students verbally engage in D-CPS through taking the conversational floor, an evolving, socially negotiated space where individuals are allowed to make contributions (Engle, Langer-Osuna & McKinney de Royston, 2014). Turn-taking describes the process whereby the conversational floor transmits among speakers. It affects the amount of opportunities that different individuals have for influencing group discussions through verbal and accompanied non-verbal contributions (e.g., Lemke, 1990). Thus, examining turn-taking structure is essential for understanding the interanimation of various voices in a group.

Gibson (2005) proposed the participation-shift (P-shift) framework to describe "the way in which people move themselves and one another onto and off the floor" (p.1,566). This framework differentiates between the various speakers, targets and third parties in human interactions, and it further identifies four categories of participation shifts (see Table 1). Turn-receiving happens when a target takes the floor offered by a speaker. Turn-claiming happens when a speaker addresses the whole group, and a third party responds to this open invitation. Turn-usurping happens when a third party usurps the floor assigned to the target by the speaker. Turn-continuing occurs when a speaker continues to occupy the floor while talking to various other individuals. These participation shifts cover all possible micro turn-taking motifs, and they can thus describe how dynamic turn shuffling gives rise to participation equity and inequity in the process.

Regarding the degrees of freedom people have to participate, both turn-receiving and turn-continuing tend to reduce the diversity of participation by limiting identity shuffling. Both turn-claiming and turn-usurping, however, strengthen the diversity of the participation structure, and thus they tend to increase the complexity of turn-taking patterns. Individuals who prefer different types of turn-taking may have different individual characteristics. Little research has been done on this issue. Tsvetkova, Garciá-Gavilanes and Yasseri (2016) did one similar study on how individual characteristics affect their reverting behavior patterns on Wikipedia. The authors identified six two-event temporal motifs to describe various behavioral patterns among the reverters and the reverted users. These researchers found that the reciprocal motif (A reverts B, and B reverts A back, AB–BA) usually happened between participants of equal status. Senior Wikipedia editors tended to perform continuous reverts (A reverts B, and A reverts C, AB–AC), and were likely to be reverted by either low-status editors or by others of equal status (A reverts B, and C reverts A, AB–CA).

Table 1: Participation shifts as defined by Gibson (2005).

Participation shift	Formula[a]	Illustration	Description
Turn-receiving	AB-BX		A talks to B, then B talks to X (X could be A or the group).
Turn-claiming	A0-BX		A talks to the group, then B talks to X (X could be A or the group).
Turn-usurping	AB-XY		A talks to B, then to X (X is not B or A) talks to Y (Y could be A, B or the group).
Turn-continuing	AB-AX		A talks to X (X could be the group), then A continues to talk to Y (Y could be the group).

a. The formula denotes the following: (speaker) (target) – (third party) (target of third party). The group is denoted as 0. X and Y represent people other than the neighbouring speaker and target.

The present explorative study tries to shed light on turn-taking approaches by first focusing on turn-usurping. Turn-usurping involves stronger agency than turn-claiming due to the usurper's self-nomination as well as the overlook of last speaker's nomination. It is an approach that an individual actively create participation opportunity rather than passively take a given one. Therefore, it represents a seemingly disruptive turn shuffling approach in D-CPS. However, to the best of my knowledge, this turn-taking approach hasn't been sufficiently explored in existing literature. I did not find relevant studies in addressing how turn-usurping might affect the process of group discussion and whether individuals who prefer usurping turns might have some specific characteristics. Therefore, the present study particularly aims to explore:

1. How does turn-usurping affect the social structure of D-CPS?
2. Who is likely to usurp a turn in D-CPS?
3. What are the intentions for students to usurp a turn?
4. How does turn-usurping shape the flow of group discussion?

Method

Participants and procedures

This study was conducted in a primary school in a city of mainland China. Participants were 168 fourth graders from five classes (41% females, 59% males, aged from 8 to 12). The teachers helped organize the students into groups of four, making gender and prior mathematics grades as balanced as possible. To ease the effect of task structure on individual participation modes, the present study designed three structured, open-process mathematical problems with various difficulties levels. Each group was given 30 minutes to collaboratively solve these three problems in a normal classroom setting. During the test, teachers or the researcher did not moderate group discussions except for clarifying task instructions or maintaining classroom discipline.

After the test, students independently completed a questionnaire concerning their demographic information, mathematics learning enjoyment, mathematics self-concept, and social anxiety. Both measurements on self-concept and learning enjoyment were measured through four-point Likert scales adapted from the TIMSS 2015 questionnaire for fourth graders in Taiwan (Mullis & Martin, 2013) (1 = *strongly agree*, 2 = *somewhat agree*, 3 = *somewhat disagree* and 4 = *strongly disagree*). Social anxiety was measured using the 10-item Chinese version of the Social Anxiety Scale for Children–Revised (La Greca & Stone, 1993). The students were asked to indicate the frequency of specific behaviors on a three-point Likert scale (1 = *always do this*, 2 = *sometimes do this*, 3 = *never do this*). The measures had a relatively high internal reliability, as indicated by Cronbach's alpha values for social anxiety (α = .835), mathematics enjoyment (α = .734) and mathematics self-concept (α = .882) (Tavakol & Dennick, 2011).

Data analysis

Written solutions submitted by the groups were graded according to a standard scoring criteria which considered the correctness of the final solution first and then awarded partial credit for solution steps informed by group discussion audios if the final answer was wrong.

Group discussion audios were transcribed turn by turn. If a speaker paused and then continue to speak, her utterances were viewed as happening in one turn. Therefore, turn-continuing is not considered in the present study. All transcripts of group discussions were coded according to the participation shift framework by two trained coders. The decision tree for identifying the target interlocutor was as follows:

Does the speaker explicitly name the target interlocutor?

Yes, code it as the named interlocutor.

No. Does the speaker use *you* in the utterance?

Yes, code it as the last speaker.

No. Does the speaker use *we* in the utterance?

Yes. Is there any clue indicating *we* not representing the whole group?

Yes, code it as the inferred target.

No, code it as Group.

No. Does the utterances belong to a flow of discussion with one specific interlocutor?

Yes, code it as the specific interlocutor.

No, code it as Group.

Participation shift type was automatically generated through Excel after target interlocutors were determined (see Table 2). Two coders separately coded three groups randomly selected from participants and achieved an acceptable level of inter-rater agreement (*Kappa* = 0.692; Landis & Koch, 1977). All disagreements over coding were resolved through negotiation. One coder then finished the coding of all the left groups.

Table 2: Sample data coding

Turn	Speaker	Target	Content	Participation shift type
42	Gan	Group	8 divided by 2 equals 4.	
43	Gu	Gan	Why? Their prices may not be the same.	Claim
44	Gan	Gu	8 divided by 2 equals 4. Listen to me (5.0), 8 yuan …	Receive
45	Xun	Gan	Gan, I wanna ask a question (…) ((in a muffled sound))	Usurp
46	Gan	Xun	It means 8 equals one popsicle and one ice cream.	Receive
47	Gu	Group	So, how can we calculate the prices of one popsicle and one ice cream?	Usurp
48	Gan	Gu	One popsicle …	Claim
49	Si	Group	I think we can calculate like this.	Usurp
50	Gan	Si	Say it.	Claim
51	Si	Gan	2, 8, 16. That is two popsicles and two ice creams. Then 22 minus 16 equals two popsicles. Then divide by 2. It is one popsicle.	Receive

The present explorative study adopted a mixed method approach. Quantitative analysis was used to address the first two research questions; qualitative analysis was used for the last two questions. The qualitative analysis only targeted three representative groups to examine major intentions for students to usurp a turn and the impact of turn-usurping in D-CPS. This study adopted a grounded-theory informed coding process to identify talk moves involved in usurped turns and further extract major functions of turn-usurping in shaping group discussion structure. There was only one coder (the author) for the qualitative analysis part.

Results

Quantitative results

Quantitative analysis was conducted to examine how turn-usurping shifts affect the social structure of D-CPS and who are likely to participation through usurping turns.

There were 42 groups in total in this study. Each group produced an average of 286 turns (*SD* = 116, *min* = 104, *max* = 522) within the half hour testing period. Turn-receiving was the most common type of participation shift within the groups. Around 43% (*SD* = 10.3%) of turns shift by the current speaker receiving the floor offered by the last speaker. The percentage of turn-usurping (M = 29%, SD = 8.1%) and turn-claiming is similar (M = 28%, SD = 7.5%).

Regarding group level analysis, the incidence of turn-usurping shifts was found to be correlated with the total number of turns one group produced ($r(42) = 0.459$, $p < .01$). Furthermore, turn-usurping is significantly negatively correlated with the standard deviation of individual participation rates ($r(42) = -0.534$, $p < .001$). That is, the higher percentage of turn-usurping in a group, the more equal of individual participations.

At an individual level, the higher degree that an individual participated by usurping turns, the higher level of her social anxiety ($r(144) = -0.204$, $p < .05$), the lower of her prior mathematics grade ($r(144) = -0.281$, $p < .01$), the lower of her prior Chinese grade ($r(144) = -0.332$, $p < .001$) and the lower level of her self-concept in mathematics ($r(146) = -0.225$, $p < .01$). That is, turn-usurpers were more likely to be those with low intellectual status, low self-concept and high social anxiety.

Qualitative results

Qualitative analysis was conducted to examine underlying intentions and the impact of turn-usurping shifts through the scrutiny of three concrete groups. The three groups were selected based on their representativeness of interaction intensity and final solution quality: groups that discussed a lot and achieved a good solution (Talkative-Good), groups that discussed few and achieved a good solution (Quiet-Good), and groups that discussed few and achieved a bad solution (Quiet-Bad) (see Table 3).

Table 3: Characteristics of three selected groups

Group	Talkative-Good	Quiet-Good	Quiet-Bad
Number of turns	361	173	126
Score of group solution	7.67	8.33	3.00
Number of turn-usurping	122	56	33
Average prior mathematics grade of members	105.50	94.75	107.33

Through examining turn-usurping shifts in these three groups, the present study found that turn-usurping shifts seldom caused interruptions of the last speaker. The percentages of interruption were smaller than 10% across three groups.

Major intentions of these turn-usurping shifts were explored through an open coding process. It was found that students usurped a turn mainly to *add on* previous speaker, initiate a turn to *express new ideas* or *propose* some action plans, jump in to *regulate* problem solving procedure and group functions, *disagree* or *agree* with someone, and initiate a *question* (see Figure 1). In addition, students in the Talkative-Good group usurped a lot of turns to *repeat* the last speaker which was not the case in the two quiet groups. A further investigation showed that *repeat* happened frequently when one student wrote down the solution while the other three kept informing him/her on what to write down. Meanwhile, students in the Quiet-Bad group usurped turns mostly to propose action plans, regulate collaborations, initiate *off-task* utterances, and *express emotions*; while there was no agree- or disagreement compared to the other two groups with good solutions.

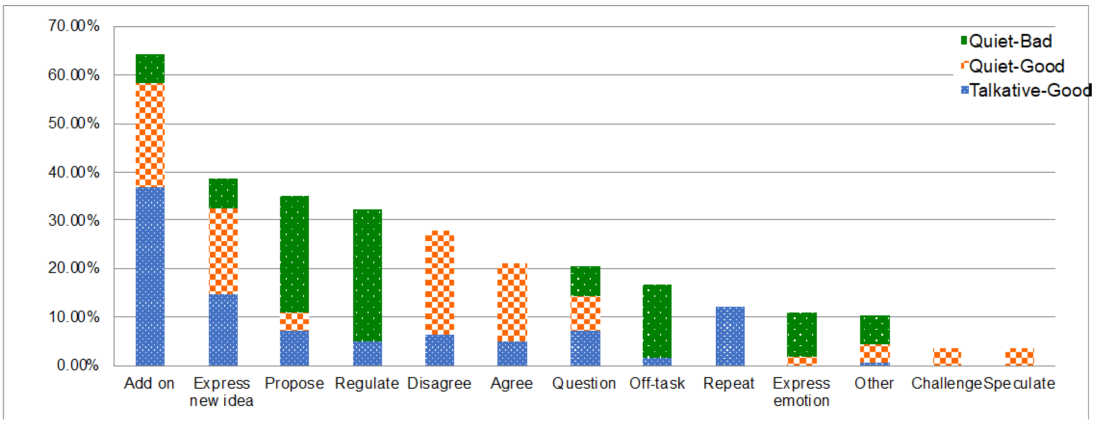

Figure 1. Distribution of major intentions of turn-usurping shifts in three representative groups.

The present study further examined the Quiet-Good group in solving the second problem to illustrate the facilitative and constructive functions of turn-usurping in D-CPS process. The second problem featuring *snake* requires students to propose three solutions to calculate the number of stones a sinuous snake will occupy when it spreads its body (see Figure 2). This problem (item ID: M051006) was adapted from the Trends in International Mathematics and Science Study (TIMSS) that was conducted in 2015 (TIMSS & PIRLS International Study Center, 2015). It mainly requires students' reasoning ability rather than their specific content knowledge.

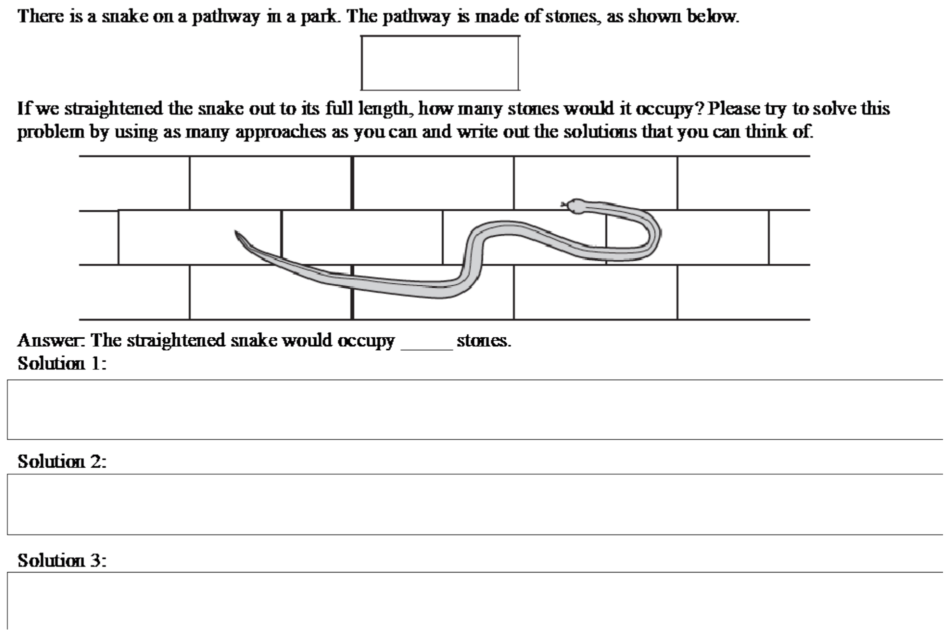

Figure 2. A translated English version of the snake problem.

The Quiet-Good group totally generated 51 turns in solving this problem. Four members' characteristics and participations were shown in Table 4. Sun was nominated as the group leader throughout discussions possibly due to his academic advantage. Qiu is academically as advantageous as Sun. While Yan and Chen position in a relatively low academic status. In the process of solving the *snake* problem, Chen and Sun accessed to the conversational floor mainly through receiving turns from others. Qiu had a balance in involving three types of participation shifts; while Yan participated in the discussion mostly through usurping turns. Yan produced the least amount of turns as well.

Table 4. Characteristics of four students in the Quiet-Good group

Pseudonym of the speaker	Yan	Chen	Sun	Qiu
Age	11	11	10	11
Gender	Female	Female	Male	Male
Recent mathematics grade[a]	88.0	81.0	106.0	104.0
Recent Chinese grade[a]	93.5	89.5	114.5	113.0
Mathematics self-concept[b]	2.78	3.00	3.63	3.78
Mathematics enjoyment[b]	3.44	4.00	3.89	4.00
Social anxiety[c]	1.900	1.500	1.200	1.300
Number of occupied turns	6.00	16.00	17.00	12.00
Percentage of turn-usurping	67%	38%	18%	33%
Percentage of turn-receiving	17%	50%	53%	42%
Percentage of turn-claiming	17%	13%	29%	25%

a. The maximum score is 120.
b. Four-point Likert scale. The maximum score is 4.
c. Three-point Likert scale. The maximum score is 3.

The selected excerpt happened when students tried to think about one solution for the *snake* problem (see Table 5). The qualitative analysis found that this discussion segment revealed various functions of turn-usurping shifts in moving forward and complexifying the group discussion. First, turn-usurping could help open a new dialogic space through initiating new questions (turn 32) or expressing new ideas (turn 37). At turn 32, Yan jumped in and initiated one question to the whole group on whether the small tongue of the snake in the picture should be counted in. This question got an instant response at the following turn which made all group members clear with target length of the snake. At turn 37, Qiu interrupted the arguments on whether the snake occupies three or five stones and proposed one new answer: four stones. This new idea stimulated reflections on previous answers and initiated a new discussion thread on the appropriateness of the answer four.

Second, turn-usurping could also help jump back to previous arguments (turn 34). Sun suggested the whole group to think over again at turn 29 and held back Chen's utterance at turn 31. At turn 34, Chen justified her previous idea of three stones and challenged Sun's answer of five stones. She usurped the turn to continue her utterance at turn 31 and strengthened her arguments at turn 34 which helped shift discussion back to previous unsettled divergence of views between Sun and her.

Third, turn-usurping could diverge the discussion flow through expressing disagreement (turn 42). At turn 42, Chen jumped in to disagree with Qiu's solution which contrasted with Sun's hesitate *yes* towards Qiu at the previous turn. This stimulated Sun to express clear attitude towards Qiu's answer and add on Chen's disagreement at turn 43. Such two continuous turn-usurping shifts involved disagreement and add-on which helped refine existing solutions and stimulate new ideas.

Table 5: How many stones would the snake occupy? Discussion segment in the Quiet-Good group.

Turn	Speaker	Target	Content	P-shift	Intention of usurping
29	Sun	Group	Then think it over again. We think about how to calculate it on earth.	Receive	
30	Chen	Chen	If, if you are right…	Claim	
31	Sun	Chen	Think it over first ((Sun interrupted Chen)) (2.0)	Receive	
➡ 32	Yan	Group	Does the tongue of the snake count or not? ((in low voice))	Usurp	Question
33	Qiu	Yan	It does not count.	Claim	
➡ 34	Chen	Group	I think it should be three stones because the body of a real snake is not that big at all. If it was five stones and each stone is long, how could it be possible?	Usurp	Justify Challenge
35	Sun	Chen	If it was not five stones, it could not be three stones neither because it is crooked here.	Claim	
36	Chen	Sun	But I moved it here like this just now. I did like this after moving it here. Therefore, the crooked part has been counted in.	Receive	
➡ 37	Qiu	Group	I think it is four stones.	Usurp	New idea
38	Sun	Qiu	Why?	Claim	
39	Chen	Qiu	Four stones are somewhat::	Usurp	Other
40	Qiu	Group	Move the head of the snake here, and then move here, then it reaches here after being straightened.	Receive	
41	Sun	Qiu	Yes::	Claim	
➡ 42	Chen	Qiu	If it was straightened, the tail could reach here at most.	Usurp	Disagree
➡ 43	Sun	Chen	Correct if being straightened. Straighten it, and it means it will reach here, right?	Usurp	Add on
44	Chen	Sun	Group leader ((Sun)), I have another idea that is we hypothesize it was several meters long, hypothesize::, hypothesize::	Receive	

Discussion and conclusion

Turn-usurping is one approach of turn-taking where a speaker usurps the conversational floor which has been assigned to someone else by the last speaker. This study presents a concise and very first examination on turn-usurping in D-CPS in terms of its impact on social structure, features of its actor, underlying intentions, and its impact on the interaction process. The findings suggest the positive impact of turn-usurping on maintaining participation equality and its constructive functions in moving forward and complexifying group discussions.

Turn-usurping and participation equality

The present study revealed a positive correlation between the percentage of turn-usurping in one group and the equality of individual participations. This is possibly due to the disruptive nature of turn-usurping. Human interaction is reciprocal (Blau, 1964; Gergen, Greenberg & Willis, 1980). If people talk specifically to someone, there is always an expectation of feedback from the same person. This is also demonstrated in the present study that turn-receiving is a robust turn-taking approach. Continuous turn-receiving shifts tend to cause a locally closed interaction chain unless speakers could consciously involve other members which, however, is a high-level competence that students need to be explicitly taught or guided (King, 2008; Michaels & O'Connor, 2009). In addition, the possible status problem in a group might worsen this situation because students tend to address frequently to the high-status students which can easily cause social dominance or isolation (Cohen & Lotan, 1995, 2014). Turn-usurping as a disruptive turn-taking approach does not follow the usual organization rules of turn-taking (Sacks, Schegloff & Jefferson, 1974). It reflects speaker's strong agency and tends to break current reciprocal turn-taking sequence and initiate a new chain of reciprocal conversation.

This study also found that students who participated mostly through usurping turns were likely to be those with low intellectual status, low-level confidence in mathematics and high-level social anxiety, which indicates the existence of status problem in the present study. Low-status students were seldom addressed by other members and fought for most of their turns in the discussion. This is against the essential premise of dialogic interactions. Genuine dialogue requires the equal rights of various voices (Bakhtin, 1929/1984). Such emphasis on equitable interactions reflects the intrinsic ethical considerations of the dialogism theory (Matusov et al., 2019). Instead of aiming at reducing achievement difference, equity in learning interactions emphasizes the construction of equitable relations among people (Boaler, 2008). Since turn-usurping currently is the major participation approach of low-status students, it seems reasonable that high rate of turn-usurping was associated with higher participation equality.

Constructive functions of turn-usurping

Benefits of turn-usurping also reflect in its constructive rather than disruptive impact on group discussion. The study found students mostly did not interrupt the last speaker when usurping a turn although they overlooked last speaker's allocation of the conversational floor. Therefore, turn-usurpers also show respect for the last speaker by allowing her finishing the turn and smoothly taking up the next turn to contribute.

Furthermore, students tend to produce high-quality utterances in a usurped turn although some turn-usurping shifts might involve off-task behavior. This is possibly because of the strong agency of students when they usurp a turn. A turn usurper possibly thinks long and hard before jumping in the discussion or blurt out disagreements or queries stimulated by the speaker. Therefore, utterances produced through turn-usurping are more likely to involve productive talk moves (King, 2008; Lazonder et al., 2003; Teo & Daniel, 2007). These productive talk moves in a usurped conversational floor further help manage and shift dialogic space in group discussion (Wegerif, 2007) including initiating a new dialogic space, jumping back to the previous one, or diverging the current one. Therefore, turn-usurping indicates a potential transition point in D-CPS and deserves further investigations in the future.

Practical implications

Previous studies have established that to best enable the success of a collaboration, there should be no significant difference among individual participations in collaborative problem solving (Asterhan & Schwarz, 2009; Dillenbourg et al., 2016). Its absence may lead to information loss, dominance by a majority of the team members or limitations on a team's potential to perform various tasks (Borge & Carroll, 2014; Woolley, Chabris, Pentland, Hashmi & Malone, 2010). The present study briefly demonstrates the positive effects of turn-usurping shifts in mitigating participation inequality and facilitating group discussion. It is thus practically meaningful to encourage students to freely jump right in group discussion through actively usurping turns in D-CPS activities.

In addition, turn-usurping turn out to be a major approach for low-status students to participate in the present context. It is thus also practically necessary to encourage students to monitor whether a turn-usurper has been isolated in discussion. Based on insights of the complex instruction approach (Cohen & Lotan, 1995), teachers could also assign competence to turn-usurpers through publicly praising the intellectual contributions in a usurped turn and arousing peers' attention to this contribution. The equity of learning interaction emphasizes the fairness of accessing to the conversational floor (Shah & Lewis, 2019). In addition to encouraging the behavior of turn-usurping whereby low-status students create participation opportunities for themselves. Teachers can also guide students to talk specifically to low-status students so that low-status students could get more participation opportunities.

The present study is inevitably limited in some ways. There were only three representative groups selected for the qualitative analysis part which aimed to address the last two research questions. Furthermore, the author was the only coder for the qualitative analysis. Therefore, more data and stricter coding process should be involved to further validate the current explorative findings. In addition, the current study was contextualized in Chinese culture background. Further research is also needed to examine whether turn-usurping features might differ across different cultures.

Intersections of the Political and the Scientific: Examining Ideological Practice in Science Class

Lynne Zummo, University of Utah, lynne.zummo@utah.edu

Abstract: In current polarized times, political ideologies shape how we act and speak, yet are given little attention in both the learning sciences and in science education, where they hold particularly damaging ramifications for disciplinary learning. This study argues for attention to political ideologies, or shared systems of representation that guide how we interact within governmental, electoral, and political spheres. Integrating neo-Marxist philosophy of ideology with notions of cultural practices, this study uses discourse analysis to explore the role of political ideologies in discourse as grade 9 US science students learn about climate change. This work identifies political ideologies prevalent in a science classroom. It examines ideologies' intersection with and divergence from scientific disciplinary engagement. This research demonstrates the role of political ideologies in youth sensemaking.

Introduction

Today, political ideology shapes how we act, speak, and experience the world, particularly around contentious science issues, such as climate change and COVID-19. The influence of political ideology on adults is clear, yet science classrooms tend to treat youth as ideology-free. Further, learning occurs at an intersection of heterogenous meaning-making practices (Rosebery, Ogonowski, DiSchino, & Warren, 2010); leaners engage in diverse ways of making sense of the world, many not scientific. As humans, such practices always involve ideologies, or systems of taken-for-granted assumptions that shape how we speak and act. In the polarized times of 2020, political ideologies are especially prevalent in sensemaking. Although discussed rarely, practices that enact ideologies, particularly political ideologies, have ramifications for science learning. This study investigates political ideologies embedded within students' discourse. Analyzing classroom discourse, this study takes a step towards understanding ideological practices that arise interactionally and influences on science learning.

Conceptual framework

As humans, we make meaning of our worlds through cultural participation (Rogoff, 2003). Cultural practices are related to context; as context shifts, so do the practices that constitute that culture. As a person tends to participate in multiple cultures, one typically makes meaning of the world through a diversity of practices, relevant to the many cultures to which they belong. This heterogeneity of human cultural practices is fundamental to learning, as learning happens when diverse meaning-making practices intersect (Roseberry et al., 2010).

Ideology

Drawing on Philip, Gupta, Elby, and Turpen (2018), I argue that the heterogenous cultural practices students bring to classroom learning involve ideology and that such practices hold implications for learning. Grounded in Althusser (1971) and Hall (1985), I view ideology as the shared systems of representation through which we live our lives. Furthermore, I build on Althusser's assertion that it is through human action and speech that ideology comes to have "material" existence. In this sense, Althusser viewed ideology as practice, living out in the rituals of communities and institutions. Cultural practices thus reflect and reproduce ideology. Drawing on Althusser, this study views schools as places where ideology gets reproduced but also takes on Hall's dialogic lens, which offers a vision of school as a place not just of ideological reproduction but also one of ideological re-articulation—where current connections of an ideology are broken and new ones created, as multiple discourses intersect and ideologies are continually reformed. I apply this lens, asking about what ideologies emerge in a science classroom and how those ideologies get reproduced, contested, and rearticulated.

Defining political ideologies

This study uses the concept of political ideologies, defined as the shared systems of representation through which we understand political institutions and our relationships to them. These shared systems are ones that allow us to hold assumptions about governmental, policy, and electoral systems and our actions related to those systems, as well as the distribution of social goods made possible through those systems. Political ideologies and related cultural practices are quite salient within US culture today, as seen in vitriolic public political debate and trends of deepening political divisions. Because of this salience of political ideologies, I argue for the necessity of its investigation in classroom-based learning. Science classrooms in particular are critical places in which to understand political ideologies, as cultural practices enacting political ideologies can pose peril to science, given that US conservative political ideology is increasingly associated with distrust of science (Gauchat, 2012). Yet, research in science learning tends to give little attention to ideology, an inattention at odds with the reality of the current social landscape. The few studies that have considered ideology reveal evidence for its salience in youth scientific reasoning (e.g. Walsh & Tsurusaki, 2018; Zummo, Donovan, & Busch, 2021).

Ideology & learning

Research has conceptualized learning as trajectories of increasing proficiency in cultural practices (Rogoff, 2003). To new situations learners bring a set of heterogenous practices with which to make meaning, and learning occurs as these practices intersect. The practices learners bring are inextricably tied to the ideology that shapes their lives. Cultural practices, which occur in social contexts, mediate the materialization of ideology (Hall, 1985); what people do and say facilitates the existence of ideologies in the material world. These words and actions, tied to ideology, influence the heterogenous practices that individuals use to make meaning. Learning and ideology are thus inextricably linked, as they are both tied deeply to how we engage with ideas and each other and how we navigate and make meaning of the world (e.g. Philip et al., 2018).

It is crucial to investigate practices linked to ideology and their influence on science learning for two key reasons. First, the emergence of ideology in classrooms can influence what students learn (e.g. Philip et al., 2018). What concepts get surfaced, reproduced, and rearticulated in the classroom social space is linked to what gets learned. Second, a key goal of science education is for students to use scientific meaning making resources to participate in the broader world (Osborne & Dillon, 2008). Yet, for many adults in the US, practices shaped by ideology, specifically political ideology, preclude scientific ways of making meaning around polarized issues, such as climate change and COVID-19. It is the responsibility of science education to shift this pattern so that scientific meaning making resources are not as readily relegated.

Language & discourse

Language and discourse mediate both science (a cultural practice of knowledge production) and the enactment of ideology. Language shapes the knowledge produced through cultural practices of science (Norris & Phillips, 2003; Vygotsky, 1978). Similarly, modern standards for science education are built around language-mediated practices that produce knowledge, such as arguing from evidence and building explanations (e.g. Achieve, 2013). This concept is mirrored in research on discourse-centered classrooms (e.g. Berland & McNeill, 2010) and recognition of the social construction of science knowledge (e.g. Kelly, 2007). In this view, knowledge production is mediated by not just an individual's language but by the discourse of the social classroom. The result is discourse-rich science classrooms in which knowledge is produced and mediated by what students say and do.

Language and discourse also mediate enactment of ideology (Bakhtin, 2010; Hall, 1985), as they allow for its material registration. Practices that make material ideology are mediated by language—the same language used to mediate meaning making in science classrooms. It is thus important to analyze classroom discourse to understand both how youth engage in disciplinary practice and how ideology, materialized through practice, influences disciplinary practice. Analysis can elucidate how scientific and ideological practices intersect, challenge each other, and diverge. To understand the role of ideology in meaning making, I look to classroom discourse, asking: 1) What political ideologies are prevalent in a 9th grade science class studying climate change? 2) In what ways do political ideologies and scientific disciplinary engagement intersect and/or diverge?

Methods

Context, participants, & data collection

This study took place in two grade 9 science classrooms in a US city, both taught by Mr. Thompson, an experienced teacher. Students came from a diversity of backgrounds, including socio-economic, racial and ethnic, and language backgrounds at a public school serving a socioeconomically diverse neighborhood. This study examined student discourse within several whole class and small group discussions. All discussions occurred within a curriculum unit on climate change in which students engaged in scientific practices, such as analyzing and interpreting data, to construct disciplinary content knowledge about global climate change. However, this study examined only discourse that took place outside of scaffolded activities. Data sources were audio recordings of: 1) unplanned, open-ended whole class discussions, and 2) small group activities in which students were not explicitly asked to use scientific practices. These data were selected because students were *not* specifically asked to use scientific concepts or practices; students were perhaps more likely to draw on heterogenous ways of making meaning used in their lives beyond school. Approximately 500 minutes of discussion was analyzed.

Data analysis

I transcribed data at the level of spoken discourse and used transcripts for discourse analysis (e.g. Gee, 2014). This process involved developing two coding schemes (Miles, Huberman, & Saldaña, 2014): one to characterize political ideologies and one to characterize disciplinary engagement.

Analytic framework 1: Ideology in pieces

To characterize political ideologies, I developed an emergent coding scheme using the analytic lens of Philip's (2011) ideology in pieces. Merging diSessa's (1993) theory of conceptual change with Hall's (1985) notion of ideology, Philip employed this lens for analysis of ideological sensemaking. This lens conceives of "pieces" of ideology that individuals use to make sense of the social world. These *naturalized axioms*, or taken-for-granted assumptions about how we live together, form ideologies. Through these axioms ideology is made material. Through axioms' articulation and re-articulation, individuals sustain, investigate, and challenge various ideologies. Philip theorized this framework to explain sensemaking about racialized contexts, arguing that individuals tend to rely on naturalized axioms when making meaning of race and racialization. I argue that a similar framework can explain sensemaking about politicized contexts, particularly when those politicized contexts are situated within a science learning experience, such as when studying climate change. While the words "political" and "politicized" can hold many meanings, in this study I use them to describe the ideologies that guide our governmental, policy, and electoral systems and our actions and interactions related to those systems. This definition includes ideologies guiding the two dominant political parties (Democratic and Republican), their stated positions, and their underlying tenets, as well as common discourses used by party leaders. To understand what political ideologies were prevalent, I coded for "pieces" of ideology, inferring naturalized axioms from students' discourse when they made assumptions about reality or about what is desirable. From naturalized axioms, I interpreted the broader ideology guiding axioms. Through an iterative process, I developed a codebook to characterize axioms and ideologies. Additionally, I coded for whether the speaker, in using the axiom, sustained, interrogated, or challenged the axiom and/or broader ideology. A selection of the finalized coding scheme can be seen in Table 1. Codes were applied at the level of talk turn whenever naturalized axioms were salient.

Table 1: Selection of ideology codebook.

	Definition	Naturalized axiom (code)
Individualism	A prioritization of individuals' rights over those of the collective; prioritization of oneself or one's immediate community	An issue is not a problem until it affects me or us
		An issue is not a problem until everyone notices
		Laws should not limit individuals' rights
		Individuals have rights to resources
		Negative consequences are excusable if they affect only a minority of people
Denialism	An ideological space in which denial of certain phenomena or observable events is normalized	People either believe or deny phenomena
		Belief and denial are related to politics
		Some phenomena are either real or a hoax
		Belief and denial are intractable
Economism	A prioritization of the economy; centering the economy, money, and market forces as of primary importance; an ideological space in which capitalism is normalized	The marketplace works
		Money is compelling
		Job creation is key
		Inequality is normal

Analytic framework 2: Productive Disciplinary Engagement

To understand scientific disciplinary engagement as it co-occurred with emergence of political ideology, I used an analytic lens built on Engle and Conant's (2002) productive disciplinary engagement (PDE), through which, Engle and Conant argued, the social construction of scientific knowledge occurs. Disciplinary engagement reflects "contact between what students are doing and the issues and practices of a discipline's discourse" (Engle & Conant, 2002, p. 402). Thus, I define disciplinary engagement as participation in the social construction of scientific knowledge—a process that involves a range of practices, including arguing from evidence, constructing explanations, analyzing trends, using quantitative reasoning, and critiquing others' ideas. To characterize disciplinary engagement, I developed coding scheme informed by prior work on the practices that constitute scientific knowledge construction (e.g. Achieve, 2013; Ford & Forman, 2006). I began with this *a priori* set of disciplinary practices as codes and then refined codes through engagement with the data. Codes were applied at the level of talk turn only when there was substantial evidence for engagement (e.g. Engle & Conant, 2002).

Results

RQ1: What political ideologies are prevalent?

Table 1 shows ideologies that emerged in all analyzed discussions: individualism, denialism, and economism. Ideologies that emerged less frequently were: imperialism, communitarianism, scientism, and technocentrism.

Individualism

A core tenet of US Republicanism (e.g. Hoover & Nash, 2016), individualism prioritizes the rights of individuals. Adherents tend to be more concerned with individuals' freedoms than the common good (Kahan et al., 2011); individualism anchors one end of a spectrum on the other end of which is communitarianism, which prioritizes the collective. Although associated with US Republicanism, individualism underlies neoliberalism, which shapes our modern political and economic system. In this classroom, individualism emerged through naturalized axioms used for sensemaking about the effects of climate change, who experiences those effects, and to what degree. An example can be seen in a whole class discussion that occurred the first day of the climate change unit.

Starting the discussion, Tony asked "When will it EVER affect us?" Emphasizing "EVER", Tony expressed dismissiveness, suggesting that climate change was not a problem for him or the people surrounding him. This move evidenced a naturalized axiom that an issue is not truly a problem until it affects oneself or one's community (Table 1). Reflective of individualism, this comment shows Tony prioritizing his own experience, in which he does not see effects of climate change. This comment makes material individualism, for if one makes sense of the world through individualism, and one is not personally affected by a shifting climate, then the effects of climate change are likely unproblematic. Tony's comment was met with a variety of animated responses. Several students challenged the individualist ideology made material by Tony. For instance, Arianna immediately responded by shouting "When we don't have a planet to live on!" Others acted to sustain it. For example, in response to Arianna, Nigel resurfaced Tony's individualism by saying "It's not affecting ME," again making material a system of representation in which the individual in central.

Denialism

Denialism emerged through several naturalized axioms (Table 1). In this classroom, denialism was a way of making sense of the social world that involved constructing some phenomena—specifically climate change—as something to be believed or denied. It is not that in making material this ideology students denied climate change, but, rather, that climate change was represented as something that can be denied. Denialism reflects a deep history of climate change in the US as a source of political divide, with skepticism amplified by prominent Republican politicians (Dunlap et al., 2016). An example can be seen in one small group's collaborative work on the first day, as they were engaging in a discussion-based activity designed to elicit prior knowledge. The students shared their responses to an earlier prompt of "What do you know about climate change?" (Transcript 1)

1.1	Arianna	Okay, tell me what you--
1.2		It's real, and it's not fake
1.3	Mason	It's real because--
1.4	Arianna	Zach, what else did you have?
1.5	Zach	I have Donald Trump doesn't believe it.
1.6		I don't know, I didn't write down a whole lot.
1.7	Arianna	Okay, we can--
1.8		Let's change that to political
1.9		Political parties claim that it's fake
1.10	Zach	Yeah
1.11	Arianna	That it's fake and that it's propaganda for Democrats
1.12	Zach	Yeah, that's basically it.

In asserting that climate change is "real" and "not fake" (Line 1.2), Arianna aired the implicit assumption that some people do not "believe" in climate change, thereby communicating that climate change is something to be believed in. While well-intentioned, her comment conveyed the idea that viewing climate change as fake remains an option for some, perhaps just not for these students in this moment. It framed climate change as something whose reality is contested, making material an ideology in which some phenomena are seen as real and others as fake. Zach's response and Arianna's following reaction together surfaced another naturalized axiom often articulated with statements of "belief". This axiom assumes that politicians are central figures in "belief"; and, the belief/denial spectrum correlates with political affiliation. By asserting that Donald Trump "doesn't believe it" (Line 1.5), Zach aired this axiom, sustaining ideology of denialism.

Economism

Economism was evidenced through students' prioritization of the economy, capitalism, and profit-generation (Table 1). An example can be seen in Transcript 2, when students in a small group discussed potential solutions.

2.1	Willa	I guess
2.2		Make electric cars more affordable so that more people are able to buy them
2.3		And umm…
2.4		I put--
2.5		If possible make large buildings and factories switch over to solar panels
2.6		If it would not pose a huge threat to their business
2.7	Ty	Okay
2.8		So for mine I did
2.9		Geothermal plants
2.10		Cause that's very efficient
2.11		Creates jobs

Willa put forward her idea for a solution, an idea grounded in the broader ideological context of capitalism—that if goods, such as electric cars, are more affordable, more people will buy them. This solution for climate change is one that sustains current economic ideology by leveraging naturalized axioms about the marketplace (Table 1). Willa continued to make material economism as she brought up industry regulations, saying that factories should be made to switch to solar panels "if it would not pose a huge threat to their business" (Line 2.6). With this caveat, Willa prioritized profit, acknowledging that generating income remains a priority, thereby sustaining economism. Then, by positioning job creation as a benefit of geothermal plants, Ty also surfaced an axiom of economism (Table 1), while also tying potential solutions to climate change into economic ideology and sustaining economism. Similar examples can be seen across the dataset. Not typically used for extended interrogation of this ideology or for challenging it, such naturalized axioms were often used by students in ways that sustained it, such as the ways in which Willa and Ty used them—to make sense of how dealing with climate change could be incorporated into pre-existing economic structures and ideals

RQ2: In what ways do political ideologies and scientific disciplinary engagement intersect and/or diverge?

Emergence of ideologies preceding (productive) disciplinary engagement

One phenomenon observed was the emergence of an ideology preceding disciplinary engagement. The disciplinary engagement that ensued in these cases often involved an intertwining with naturalized axioms; thus, I consider these moments examples of ideology made material within scientific disciplinary engagement. One example can be seen in the whole class discussion described earlier that began with Tony's question of "When will it EVER affect us", a making material of individualism. This laid the groundwork for ensuing episodes. Following Tony's comment, several students made evidence-based arguments about climate change already being a problem, thereby challenging Tony's expression of individualism. Eventually, while pointing to evidence of ice melt, one student said that "a lot of people still think climate change is a hoax", a comment that sustained denialism. The episodes that followed moved from sustaining denialism to interrogating it, at times, through disciplinary engagement. For example, Arianna engaged in perspective taking to consider why one might call climate change a "hoax." Cameron reasoned quantitatively, saying that correlation "is not the same as causation", and used that reasoning to critique a classmate's piece of evidence about increasing forest fire intensity, thereby sustaining denialism by giving skepticism plausibility. In response, Arianna cited evidence showing that a recent large fire was not necessarily caused by climate change but then went on to draw on scientific models of climate change making conditions conducive to intense fires. Martina built on this interrogation with disciplinary engagement, saying that the fires alone one could "call it off as coincidence", yet with a higher-level analysis of other global trends, one could see significant climatic changes. Within this discussion, ideologies and disciplinary engagement were often intertwined, with naturalized axioms emerging in disciplinary engagement and used for the social construction of knowledge, as they were sustained, challenged, and interrogated by students' disciplinary engagement. Across the dataset, there was evidence for this sort of co-occurrence.

Making ideologies explicit in critique

Another trend that emerged was the making explicit of ideologies within the disciplinary practice of critique. For example, in a small group discussion that turned to the relative role of city buses in climate change, Arianna and Mason disagreed. Although naturalized axioms constituting relevant ideologies were at first implicit, as the disagreement unfolded, Arianna made assumptions explicit in critique of Mason's argument. At first, Mason and Arianna engaged disciplinarily in obvious ways via quantitative reasoning in comparing the emissions of buses to cars, yet implicitly underlying the conversation were assumptions of who should have access to the resource of public transportation. However, this assumption did not become explicit until the debate stalled and Arianna declared that "people need [buses] though, you're just not one of them". Here, she challenged the ideology of individualism that had been shaping Mason's engagement. Within this discussion, engagement early on was disciplinary, with both students drawing on quantitative reasoning and specific evidence to advance claims. It was only when this disciplinary engagement stopped progressing that Arianna pivoted to ideological engagement to challenge the individualist ideology appearing to shape Mason's engagement and to further her critique.

Ideological engagement in the absence of science

There were several cases where political ideologies emerged and led only to non-disciplinary engagement, as were there cases in which ideologies emerged and appeared to preclude further engagement. An example of the latter can be seen in a small group discussion. After Nathan asked how climate change could be fixed, John said "we can stop giving gas to f-ing China, and they can stop running their cars". Prior to this episode, the three students had been discussing the greenhouse effect and how CO_2 was altering it—an example of disciplinary engagement. Yet, with Nathan's posed question, John surfaced assumptions reflective of both individualism and imperialism, invoking assumptions about the respective roles of China and the US in causing climate change and alluding to rights to resources. John's comment about China went unresponded to; it was not part of any evident disciplinary engagement and it did not appear to spur any further engagement in general; following this episode, there were several moments of silence and then talk turned to topics unrelated to the task.

Discussion

Interpretations of this analysis rely on the theoretical concepts that ideology is made material through language and discourse (Bakhtin, 2010; Hall, 1985), and that knowledge is produced through cultural practices mediated by that same language and discourse, (Vygotsky, 1978) and, further, that this process unfolds in the social space (Philip et al., 2018; Roseberry et al., 2010). Additionally, it is within these cultural practices that ideology is reproduced, contested, or re-articulated (Hall, 1985); consequently, the reproduction and/or transformation of ideology has implications for knowledge produced through interactions in which ideology is made material. With this theoretical framework, I argue that the meaning making in which students engaged involved heterogenous practices, some of which involved political ideologies, as made material through naturalized axioms (Philip, 2011). Therefore, the knowledge produced socially through collective meaning making was shaped and informed by the ideologies sustained, contested, and interrogated. Ideology mediated students' knowledge production.

Affordances of political ideologies' emergence

Although science education has historically aimed to keep politics out of the classroom, I see potential in explicitly considering political ideologies into learning. In one class, students' interrogation of denialism led to disciplinary engagement that was, to a degree, productive. As students interrogated assumptions of denialism, many engaged in scientific practices. Political ideologies shaped knowledge production, but they did so in ways that pushed student thinking beyond the bounds of an existing ideology to question it and did so in ways that incorporated scientific practices. Furthermore, this interrogation questioned an ideology that, I argue, has limited societal response to climate change and damaged the value of science as an institution. The prevalence of denialism has built space for skepticism over climate science, allowing such skepticism to thrive and be deployed by opponents to mitigation measures (Oreskes & Conway, 2011). Although this interrogation did not quite transform or extinguish denialism, it facilitated an examination and re-articulation of it. Through the discussion, there was a movement from the need to convince others of climate change to the need to understand their perspective, thereby rearticulating skepticism as not something to be suppressed but something to be investigated and understood.

Separately, this study gives evidence for ideologies as tools in argumentation, as seen in the bus debate. Arianna and Mason first drew on quantitative reasoning to argue, but the debate eventually stalled. Arianna then made explicit ideology about the distribution of social goods. In doing so, she uncovered a new lens through which to compare her argument to Mason's. Making explicit the ideology that guided each perspective clarified points of disagreement, helping the argument progress. Notably, Arianna pivoted to drawing on ideology when attempting to critique. One potential explanation for this pivot could lie with critique, a challenging practice that could lead to the leveraging of multiple resources. Alternatively, there may be something about critique itself that surfaces ideology. Since critique involves positioning by taking a stance against an idea, it could surface facets of identity, which is linked to ideology (Althusser, 1971).

The potential for ideologies in learning builds on research in socio-scientific issues (SSI), where scholars have shown that supporting students in drawing on their own moral frameworks—cultural practices not traditionally viewed as scientific—can support science literacy (Sadler, 2009). This study expands the SSI field by going beyond moral practices to define the political-ideological, which I argue are essential to consider in a time of political extremism. When drawn on in conjunction with scientific meaning making resources, political ideology could support disciplinary engagement and learning. Yet, I recognize the potential danger of this statement and concurrently argue that it is the responsibility of science education to help youth use these practices—ideological and scientific—in tandem in ways that align with (and do not damage) science.

Problematic sides to emergence of political ideologies

The emergence of political ideology can also be problematic, as evidenced here. First, potentially damaging ideologies can be sustained and reproduced, and student discourse often sustained ideologies. One could argue that sustaining individualism succeeds in inhibiting actions that could mitigate climate change. Likewise, one could argue that the reproduction of economism is problematic, as embrace of neoliberal economics has contributed to deepening inequality (Azevedo et al., 2019). Reproduction of ideologies can limit the possibilities for real transformation in a society that is far from perfect. Second, this study suggests that political ideologies can also preclude disciplinary engagement. In many moments, drawing on political ideologies appeared to supersede engagement with scientific meaning making. With the greater sociocultural context of ideological extremism and distrust of science, this observation is problematic. This sort of practice can contribute to the uncivil, anti-science discourse that permeates current society. If we want to reduce societal schisms over science, we need to actively work against the tendency to prioritize political ideologies over scientific resources. While I acknowledge that drawing on political-ideological resources for making sense of socio-scientific issues is unavoidable (and at times beneficial, as described above), I argue that science educators have a responsibility to help students do so in ways that do not denigrate science. These findings thus move me to advocate for science education that supports youth in engaging in civic discourse. Similar to other recent calls (Allchin & Zemplén, 2020; Feinstein & Waddington, 2020), I argue that science education must help youth not only use science responsibly but also be explicit about the sources and epistemologies of their ideas, recognizing that some emerge from political-ideological realms and some from scientific. It is our responsibility to help young people understand the heterogeneity of epistemic resources used and cultural practices engaged in as people navigate the world.

Implications

As an exploratory analysis, this piece lays the groundwork for future investigations of the influence of political ideologies on disciplinary learning. It speaks to Philip et al.'s (2018) argument that ideology influences learning. To their call to the learning sciences community, I add one specifically targeted at the field of science education for attention to ideology, particularly with the heightened emphasis on learning through discourse. While dialogic classrooms are essential to meaningful, disciplinary learning, it is critical to remember that discourse is also the medium through which ideology emerges, is made material, and is reproduced, challenged, and/or rearticulated. In this way, ideology holds influence over the knowledge produced through a science learning experience. Additionally, I suggest future work to examine the relationship between ideology and identity, with attention to how this relationship operates with in scientific disciplinary engagement, such as critique. Althusser (1971) and Hall (1985) argued that ideology is inherently related to identity, as the individual gets "interpellated" by ideology. With this study illuminating the relevance of ideology to disciplinary engagement it becomes time to investigate the identity of students who with their discourse make material ideology. As for educational practice, this study suggests that making ideology explicit, particularly when it shapes scientific practice, could be valuable to classroom learning. People, including youth, will always be living out ideologies through what they say and do. Rather than ignore this reality, we, as educators, should help young people learn to be explicit about the ideological aspects of their thinking and how that might influence their disciplinary work. I advocate for civic discourse in science classrooms, so that youth learn to engage in the civil discourse with which adults appear to struggle today.

Conclusion

This study offers a step into understanding the relationship between ideology and disciplinary engagement, laying the groundwork for future research in largely uncharted territory. A key takeaway is that political ideology did emerge through student discourse and appeared to shape the knowledge being produced through social interaction. Importantly, this emergence occurred within free-form discussions when students were not explicitly asked to use science. It is well known that adults tend to rely on a constellation of cultural practices, including political-ideological practices, to make sense of their worlds as politics become an aspect of identity increasingly salient in US culture. This study suggests that youth, too, draw on political ideology in navigating science-related issues.

Exploring the Solution Generation Process in the Problem-Solving Phase followed by Instruction: How Do Learners Perceive their Knowledge Gaps?

Jinju Lee, Hanyang University, leejinju@hanyang.ac.kr
Jongchan Park, Kwangwoon University, nmb0172@gmail.com
Dongsik Kim, Hanyang University, kimdsik@hanyang.ac.kr

Abstract: This study investigates how the awareness of knowledge gaps (AKG) manifests by observing the problem-solving phase in PS-I(problem-solving followed by instruction). Comprehensively exploring the discourses of learners in this phase while seeking to categorize knowledge states around AKG will strengthen the underlying mechanism of PS-I. Understanding how AKG manifests will help pave the way for further research on how various knowledge states influence the effectiveness of PS-I, facilitating the design of appropriate instructional interventions to promote desirable knowledge states. With twelve graduate students as participants, this study qualitatively analyzes conversational discourses of the problem-solving phase and finds that students spend most of their time solving problems and seldom evaluate their thoughts, while only a few express their experience of a knowledge gap. The authors suggest categories of knowledge states around AKG and the distinctive characteristics of each category.

Keywords: awareness of knowledge gaps, problem-solving followed by instruction, qualitative content analysis

Introduction

The learning approach known as problem-solving followed by instruction (PS-I) has emerged as an attractive research area over the last decade because it may offer students productive learning experiences regardless of their initial unsatisfactory performances (Kapur, 2016). Under the PS-I approach, instructional interventions promote the learner's self-made tryouts (in the initial problem-solving phase) and use this experience to construct a strong schema that will be subsequently useful in the instruction phase (Likourezos & Kalyuga, 2017; Loibl et al., 2017). Research groups in productive failure and invention activity, which are strategies representative of the PS-I approach, have reported positive effects (Darabi et al., 2018; Loibl et al., 2017), with even more favorable effects emerging when compared to the instruction followed by problem-solving (I-PS) approach (Schalk et al., 2018).

What makes the problem-solving process in the PS-I approach unique compared to the conventional problem-solving after instruction approach? The review of Loibl and her colleagues (2017) described three mechanisms for how the external instructional event of PS-I triggers an internal state in the learner: a) prior knowledge activation, b) awareness of knowledge gaps, and c) recognition of the deep features of the target concept. The second mechanism, which is the focus of this study, is key to the efficacy of PS-I. The failure to solve a problem is ineffective if students are unaware of their failure because learners need to *know what they don't know* to be better prepared for the upcoming instruction, both cognitively and affectively (Hmelo-Silver et al., 2018). Awareness of knowledge gaps (AKG), which is a main cognitive event during the problem-solving phase, is an important aspect of the PS-I approach as it relates to the use and elevation of meta-cognition, which plays a crucial role in complex problem-solving and knowledge construction (Likourezos & Kalyuga, 2017). The knowledge gap highlights what a learner lacks and thus needs to know, thereby making the failure experience productive. However, little is known about how to support AKG.

This study starts with curiosity, asking whether a student can reach the 'knowing what they do not know' state, and if so, how this AKG manifests and whether the learner's state of AKG affects the effectiveness of PS-I. As a preliminary phase for the abovementioned research question, this study focused on how students become aware of their knowledge gap by exploring the process of problem-solving in PS-I in both deductive and inductive ways. Specifically, the current study first qualitatively examined learners' conversational discourse in problem-solving during PS-I using a deductive content analysis. Then, the authors conducted an inductive content analysis with the same talk-aloud data to classify the knowledge states around AKG. Identifying the characteristics of each state facilitates the understanding of how learners experience their knowledge gaps and how AKG manifests during problem-solving through comparisons with other knowledge states. This understanding offers practical implications for research on scaffolding strategies for positive experiences around AKG in PS-I.

Awareness of knowledge gaps in the PS-I approach research

Among PS-I advocates, researchers interested in invention activity (see Schwartz & Martin, 2004) are those who conceptualized the idea of the knowledge gap and measured it with questionnaires. Glogger et al. (2013) focused on the experience of the knowledge gap as a cognitive outcome of invention activity and assessed it using nine items on six-point self-rated scales (e.g., "My knowledge was insufficient to complete the task"). Their results indicated that invention activity increased the knowledge gap. They used a five-item version in their follow-up study and reported the same result (Glogger et al., 2015).

Subsequently, Loibl and Rummel (2014) introduced the term 'awareness of knowledge gaps'. The idea is rooted in the impasse-repair-reflect process (vanLehn, 1999) and the imperfect mental model view (Chi, 2000), which highlights the mental repair process of students when they become aware of their incapability in processing the incoming information within their current knowledge. Loibl and Rummel compartmentalized this awareness of incapability into a global awareness of knowledge gaps (i.e., "an awareness that they have knowledge gaps without being able to specify which component they are lacking", p.75) and an awareness of specific knowledge gaps (i.e., an awareness elicited during instruction by "helping them to detect differences in a more specific manner", p.75). They argued that identifying knowledge gaps may induce modifications to learners' current partial, naïve, or erroneous schemas, and suggested that instruction that compares a student's solution to the canonical solution can specify the gaps that occurred globally in the problem-solving phase. Using five items (e.g., "I lack knowledge required to solve this problem" and "I think I did not find a canonical solution for this problem", p. 81), they demonstrated that a PS-I session can trigger global AKG, with students in the PS-I group reporting more knowledge gaps than those in the I-PS group. In their follow-up studies, they emphasized comparing and contrasting activities as a remedy in specifying the knowledge gap and a connector to the next mechanism (i.e., deep feature recognition) (Loibl et al., 2017; Loibl et al., 2020).

The idea of AKG is also supported by other advocates of the PS-I approach. In his comprehensive work on productive failure, Kapur (2016) stressed the importance of differentiating relevant prior knowledge and identifying knowledge gaps as mechanisms of learning through problem-solving (see also Hmelo-Silver, Kapur, & Hamstra, 2018). Using Glogger and colleagues' (2015) questionnaire items, Lee et al. (2018) reported that supporting the problem-solving phase with meta-cognitive prompts increased AKG. Newman and DeCaro (2019) emphasized AKG as a metacognitive benefit of exploratory learning, providing guidance for students to perceive knowledge gaps. They examined whether students perceive knowledge gaps differently according to the order of instruction (i.e., instruction-first versus explore-first) and activity implemented (i.e., invention versus worked example). Finding evidence of a significant main effect and an interaction effect, they suggested providing pretests with worked examples as a supporting strategy for AKG.

However, the previous studies only dealt with global AKG using self-reported scales. Hence, how such awareness does, or does not, emerge during problem-solving is still not fully understood. As to the important role of AKG in the PS-I approach, instructional interventions for AKG arise as a remarkable research topic. In other words, the learner's experience around AKG needs to be scrutinized: Is it enough to understand learners' AKG as global AKG, or are there any other knowledge state categories around AKG? Why do some learners develop AKG, while others do not? This study investigates how AKG manifests by observing the problem-solving phase in PS-I. Comprehensively exploring the discourses of learners in this phase while striving to categorize knowledge states around AKG will strengthen the underlying mechanism of PS-I. Further, understanding how AKG manifests will open an avenue for future research to examine how various knowledge states impact the effectiveness of PS-I and subsequently design appropriate instructional interventions that promote desired knowledge states.

Research questions

1. What cognitive processes do learners experience when they assess the given problem and develop their own solution?
2. How do learners evaluate their knowledge during the problem-solving phase in PS-I?
3. How can the states of the awareness of knowledge gaps be defined?

Methodology

The main analysis method used in this study was qualitative content analysis. The advantage of content analysis lies in its ability to draw replicable and valid inferences from observed conversational discourses to their context (Krippendorff, 1980). Qualitative content analysis is an effective method for understanding and describing phenomena by creating or applying categories and concepts (Elo & Kyngäs, 2008; Mayring, 2000). Regarding the first research question, the authors first qualitatively examined learners' conversational discourse in problem-solving in PS-I using deductive content analysis. With a coding scheme adapted and revised from previous research (Poole & Holmes, 1995; Große & Renkl, 2007), students' conversation texts were categorized into one of the codes.

Based on the implications from the first content analysis result, an inductive content analysis was conducted with the same talk-aloud data after defining different analysis units to answer the second and third research questions. The knowledge states around AKG were classified, and the authors categorized several variations of how the students self-evaluated their knowledge during problem-solving. In the process, the authors open-coded the discourse data and identified the characteristics of each state through comparisons between categories.

Material and participants

With the publisher's permission, this study used the problem scenario from Kapur's (2008, pp.419-421) work, which is ill-structured and carefully designed. The problem scenario encompassed investigating a speeding case, targeting the concept of frictional force and work-kinetic energy. The first author translated the problem scenario into Korean with an American English professor who is bilingual in Korean and English. After translating the problem, the validity of the material was confirmed by a high-school physics teacher. Twelve graduate students majoring in Educational Techology were recruited from a graduate school in South Korea (nine females and three males; average age = 25), who received $5 value gift cards as a reward for their participation. The participants were randomly assigned to one of six pairs.

Procedures and data collection

The experiment followed procedures in the conventional PS-I approach, i.e., peer problem-solving followed by instruction. The participants worked with iPad Pro 2s and Apple Pencils during the experiment session to record the dialogue and notes taken during the session. The default 'screen recording mode' was used to collect spoken and written data. For the problem-solving phase, the pairs of students were each given 25 minutes to collaboratively solve the problem scenario with a peer, sharing one iPad and one Apple Pencil (see Figure 1 (a)). After the problem-solving phase, the participants individually watched an instructional video that included a lecture on the target concepts and a solution explanation for the problem scenario. As they worked individually in the instruction phase, one iPad and one Apple Pencil were provided per student. The participants were asked to watch the instructional video on the left-hand side of the screen along with the scribbled version of the problem scenario file on the right-hand side of the screen; they were able to take notes over their previous notes if necessary (see Figure 1 (b)). The spoken data in the collected recordings were subsequently transcribed into script format and used for the dialogue analysis. The written data were used in a supplementary role in the analysis of the spoken data. This study mainly focused on the discourse data generated during the problem-solving phase. Investigating the effects of the PS-I approach (e.g., post-test results…etc.) was beyond our research scope.

Data Analysis

This study used two qualitative content analyses with the same conversational discourse data: Deductive content analysis to examine the cognitive processes or aspects that the learners experienced during problem-solving, followed by inductive content analysis to categorize the different states of knowledge and define each state through comparisons between categories. As the selection of the analysis units depends on what the analysis aims to discover (i.e., in relation to the research question; Mayring, 2000), the authors selected different analysis units for each content analysis.

Deductive content analysis for problem-solving discourse

The authors adapted two coding schemes used in previous studies on student interactions (Kapur & Kinzer, 2009; Poole & Holmes, 1995) and self-explanation in learning from erroneous examples (Große & Renkl, 2007), integrating them to ensure the integrated coding scheme was sufficient to achieve the current research aim. While the coding scheme from Kapur and Kinzer (2009) reflected the multifaceted nature of student interaction, it lacked separate room for impasse-related and error-related utterances. The coding scheme from Große and Renkl (2007) provided logical and clear distinctions between those utterances. As the current study aims to explore the cognitive processes that learners experience when they solve a given problem, the authors needed to differentiate from other categories such utterances that may show a cognitive trajectory towards a different knowledge state. As a preparation phase for the content analysis, the authors divided the discourse transcript into idea units, which were selected as including words or sentences containing a context for a meaning unit in terms of each category.

The authors then conducted a preliminary coding based on the adapted coding scheme, which included the categories of *Problem Assessment, Orientation, Impasse, Solution Development, Recognition of Error, Identification of Reasons for the Error*, and *Solution Evaluation without Error Detection*. During the preliminary coding process, new categories were found, namely *Guess and Assumption, Prior Knowledge*, and *Motivation*. After closely reading the discourse transcripts, it turned out that the learners often tried to make assumptions based on contextual information about the problem, such as "I think the coefficient of friction has something to do with the weight of the car". This study created a new category for this sort of utterance, *Guess and Assumption*, because the authors believed that making assumptions could be a starting point for an awareness of a knowledge gap. Moreover, *Prior Knowledge* was added to the codes because the learners often retrieved relevant concepts when assessing the problem and generating and evaluating the solution. Aligning new information obtained from assessing the given problem with their prior knowledge can be a sign of learners revisiting their memory (Park et al. 2020) and preparing to generate a solution, which, in many cases, leads to global AKG (Loibl & Rummel, 2014). After learners realized that they needed more knowledge to solve the problem, some of them stated that they wanted to learn the need-to-know knowledge from the following instruction. The authors coded these utterances as *Motivation*. The first and second author then coded every idea unit based on the final coding scheme (see Table1). The inter-rater reliability was good (Cohen's κ = 0.74), and the final code was determined by resolving any discrepancies through discussion.

Table 1: Coding scheme for problem-solving discourse

Codes	Description	Example
Problem assessment	Mentions details of a problem, prioritizes details, makes connections between details, or provides new perspectives in interpreting aspects of a problem.	"Um... For now, I think what counts is... the total weight and time, not the total weight and the speed limit. like we thought."
Orientation	Tries to orient or guide the group's process	"Let's write down and then think about it"
Impasse	Expresses confusion, pauses for a long period, and/or states unexpected difficulty and negative monitoring	"Coefficient of friction... apply the coefficient of friction. Then the way is... (long pause)"
Solution development	Mentions a (sub-)goal, an operator, or a relevant formula, tries anticipative reasoning, and/or suggests ideas, proposals, alternatives, or rebuttals	"Distance 15, velocity 55. Shall we calculate the speed using distance velocity and time (DVT)?"
Guess and assumption	Guesses next solution steps, and/or makes assumptions on concepts and processes to assess a problem and generate and evaluate a solution	"But since high coefficient of friction means a stronger friction, doesn't it mean the brake should work faster? That's how I see it."
Prior knowledge	Activates prior knowledge and/or aligns it with new information	"Suppose the distance is 15 meters, then, um, this is X and it would be best to know the acceleration inclination, mmm F= ma..."
Recognition of error	Mentions that there is an error and/or finds an error in the generated solution	"This is 4.5 again? Maybe not, I don't think this is it, obviously, 559."
Identification of reasons for the error	Gives reasons for the errors	"I think the coefficient of friction we set here should not be 1."
Solution evaluation without error detection	Gives an evaluation of the generated solution (but does not find any potential errors)	"When we say this is 25, what's the reason for dividing it with the weight? ... I mean we divided the total distance... right? I think what we did is right!"

Motivation	States motivation to learn need-to-know knowledge from the following instruction	"I think there was something like square of the weight. 70... no 1675. I hope the video shows this part."

An inductive content analysis for knowledge state categorization during problem-solving

During the course of applying the deductive approach, new categories of the problem-solving discourse emerged in regard to learners' attempts to guess the next solution steps, prior knowledge alignment, and motivational aspects. The authors were able to identify that the utterances of these categories were presented by *some* participants but *not all* participants. Based on this finding, the authors conducted the second content analysis in an inductive manner to explore how the learners' knowledge states varied in the problem-solving phase of PS-I.

A new selection of idea units for the analysis with the same discourse data was made because the aim of the second content analysis was different from that of the first analysis, namely to analyze how learners evaluate their current knowledge and to define the states of AKG. Knowledge states in an individual learner may vary depending on different related concepts. Thus, an idea unit was selected if it included phrases representing a knowledge state around each related concept (e.g., kinetic energy variation, work-energy relation, friction)

After identifying all idea units, the first and second author conducted open coding. During the process, the coders suggested a total of eight categories, namely, a) *Knowledge not Accessed,* b) *Knowledge not Evaluated,* Knowledge Evaluated as c) *Sufficient,* d) *Intuitive,* e) *Naïve,* or f) *Uncertain*, g) *Insufficient and Unspecified Knowledge Gaps*, and h) *Insufficient and Specified Knowledge Gaps*. The coders then assigned idea units to these categories. In the discourse, explicit signs of self-evaluation (e.g., "I think we were wrong here") were rarely presented, although some remarks (e.g., "If I know the formula to use this...") could be indirectly inferred as self-evaluation. The coders used these signs as criteria to determine whether parts of the discourse belonged to self-evaluation. During the course of the preliminary coding, the *Intuitive* category was removed because self-evaluating their own knowledge as intuitive was always involved in parts of either *Sufficient*, *Naïve* or *Uncertain* (e.g., "This reminds me of energy because everything has energy, but I don't know whether we are on the right track. Do you?"), but not vice versa, in the data collected. In a similar vein, the coders agreed to integrate *Naïve* and *Uncertain* into a single code, *Naïve and Uncertain,* because both codes could be used to describe the same knowledge states in the current study. Table 2 shows the final categories identified through the analysis.

Table 2: Categories of different knowledge states around AKG

Categories		**Definitions**
a) Knowledge not accessed		Students do not mention a certain knowledge element.
b) Knowledge not evaluated		Students mention a certain knowledge element (or activate prior knowledge), but no verbal evidence of their self-evaluation of the element is found.
c) Self-evaluated knowledge	c-1) Sufficient	Students mention a certain knowledge element (or activate prior knowledge) and regard the retrieved element as sufficient to solve the problem.
	c-2) Naïve and uncertain	Students mention a certain knowledge element (or activate prior knowledge) and regard the retrieved element as naïve or uncertain to solve the problem.
	c-3) Insufficient and unspecified knowledge gaps	Students mention a certain knowledge element (or activate prior knowledge) and regard the element as insufficient to solve the problem with an expression of impasse. They do not know the exact point that they are missing.
	c-4) Insufficient and specified knowledge gaps	Students mention a certain knowledge element (or activate prior knowledge) and regard the element as insufficient to solve the problem with an expression of impasse. They know the exact point that they are missing.

Findings

The analyses resulted in two main findings. The first finding comprises a quantitative description of the analysis result using the newly developed coding scheme for the participants' talk-aloud data. The second finding presents examples of the different knowledge states around AKG.

Finding 1: Students spend most of their time solving the problem and seldom evaluate their thoughts.

According to the descriptive analysis of the conversational discourse in the problem-solving phase, over 42% of utterances out of 559 idea units in total belonged to problem assessment. All six peer groups devoted at least more than 30% of talk to assessing the problem. Students seldom engaged in meta-cognitive processes such as recognition of error (utterance count=18), identification of reasons for the error (utterance count=7), or other types of solution evaluation (utterance count=9), although they relatively often faced moments of impasse (utterance count=64), made assumptions on concepts or processes (utterance count=71), and retrieved prior knowledge (utterance count=41) when solving the given problem. The utterance frequency rate is illustrated in figure 2.

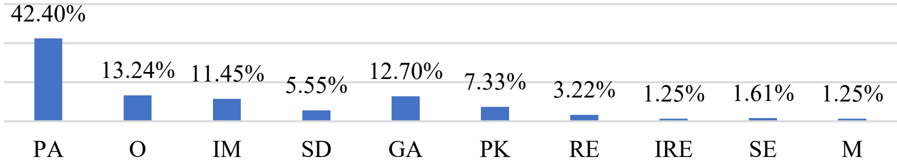

Figure 2. Utterance frequency rate.

Abbreviations: PA. problem assessment; O. orientation; IM. impasse; SD. solution development; GA. guess and assumption; PK. prior knowledge; RE. recognition of error; IRE. identification of reasons for the error; SE. solution evaluation without error detection; M. motivation.

Finding 2: Only a few expressed their experience of knowledge gaps.

The examples for each knowledge state around AKG are presented in table 3. Six categories were found in total, although only two of these were related to AKG, namely c-3 and c-4. Moreover, there were only two cases of c-3 and c-4, while several cases were found for the other categories (the current paper introduces only one example dialogue for each category due to the word limit).

Table 3: Example dialogues of different knowledge states around AKG

Categories	**Example dialogues**
a) Knowledge not accessed	N/A
b) Knowledge not evaluated	Eugine: But since high coefficient of friction means a stronger friction, doesn't it mean the brake should work faster? That's how I see it. Grey: Or in my opinion, because it's heavier, I thought the inertia would be stronger and it might have caused longer time to stop.
c-1) Sufficient	Grey: When we say this is 25, what's the reason for dividing it with the weight? Dividing it with the weight suggests, inversely, we used multiples, by multiplying the time the weight can travel, I mean we divided the total distance... right? I think what we did is right.
c-2) Naïve and uncertain	Jin: Same here. I'm just going by instinct. While going for 2.2 seconds, he braked 15 meters behind, he stopped, so he didn't cra(sh)… he went 15 meters in 2.2 seconds. John: And the force of the 1645kg is 15 meters, then? (Jin: Really?) Yeah, the car went 15m. Because the heavier the weight, the harder the friction. When it's stronger, right? So I… give up? A different method? … (long pause) Jin: This is 4.5 again? Maybe not, I don't think this is it, obviously, 559. John: But if we know the speed, ummm Jin: Shouldn't we look at the car, not the speed?
c-3) Insufficient and unspecified knowledge gaps	Lucy: Does this 3 second have any significance in the problem? Along with this, so many numbers appear in the latter part of the problem, like the km, 0.6 to 0.7, etc.? Do we have to go all mathematical with these numbers? Jane: Mathematically, but since we don't know how they're connected... (long pause) But thinking about it, 3 seconds is a very short time, then can this be an evidence that the driver foresaw this and stopped
c-4) Insufficient and specified knowledge gaps	Kim: Then, like this. This is a huge difference. Kim: But what bothers me is what we missed... Kim: There may be a way to solve the problem using the coefficient of friction on this road. Right? I feel like this was mentioned for a reason. Seo: Ah... it mentions the weather too... Kim: There's no reason to slide since it's a dry road... But because he has history of accident, it's hard to prove his innocence so we have to present a clear evidence. Seo: Coefficient of friction... apply the coefficient of friction. Then the way is... (long pause) Kim: If I know the formula to use this...

Discussion

General discussion

The current study comprehensively investigated the conversational discourse during the problem-solving phase in PS-I to identify the cognitive processes that learners undergo when solving a problem and how they reach, or do not reach, the state of AKG. To achieve this goal, this study conducted two separate qualitative analyses. Through deductive content analysis, the authors discovered that during the long period of problem assessment and solution generation, the learners sometimes faced moments of impasse and rarely found errors or reasons for the errors. It seemed that when challenged by impasse moments, learners often made assumptions about information that did not clearly align with their current knowledge. These phenomena required the addition of new categories to the coding scheme used in the previous study on PS-I (Kapur & Kinzer, 2009). The authors assumed that learners are rarely urged to revisit their memory to repair current naïve knowledge (vanLehn, 1999; Chi, 2000) in such challenging explorative problem-solving activities in PS-I. As modifications of the current partial or erroneous schema follow the identification of knowledge gaps, how learners' knowledge states vary and what makes the AKG state different from others should first be understood to support the PS-I mechanism.

Building on this emergent implication from the first content analysis, this study conducted the second content analysis in an inductive way. Based on the analysis results, this study classified the self-evaluated knowledge states around AKG as shown in Figure 3.

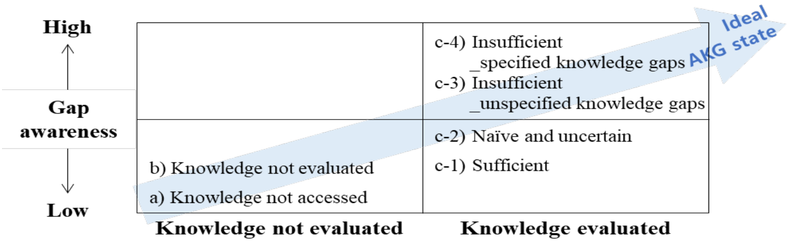

Figure 3. Classification of self-evaluated knowledge states in terms of gap awareness.

Apparently and naturally, students could not activate any relevant prior knowledge when they had no idea about a concept (i.e., a) knowledge not accessed). When a targeted concept was beyond the students' level, they kept generating irrelevant remarks. Also, in many cases, even when they activated related concepts, the students still did not perceive the existence of gaps in their ideas because they did not evaluate their knowledge structure of the concept (i.e., b) knowledge not evaluated). Regardless of the possibility that they might have perceived a gap but this was not expressed in the conversation, the context indicated that the students did not reach the state of AKG. It is hard to tell whether the out-of-focus utterances were meaningless for learning, but considering the preparatory effect of the PS-I approach, there needs to be a fence that guides students and prevents them from straying far beyond the track. Even when the students evaluated their thoughts, there were various categories of a perceived knowledge state. Some felt confident about their knowledge and consequently did not experience a gap. Some felt uncertain about their ideas or regarded their ideas as naïve, but they did not notice potential knowledge gaps or show a willingness to dwell on the uncertainties. When the students noticed that their knowledge was insufficient to solve the problem, some specifically located the lacking point, while others just felt that something was missing.

From a comprehensive view, the authors would like to aggregate their findings into the concept of AKG, which has been suggested as a key mechanism for PS-I. While it remains arguable which state in the category can be considered AKG, this study carefully suggests that the ideal AKG state, which previous PS-I research indicated as 'knowing what you don't know', is the last state of knowledge evaluation, namely insufficient and specified knowledge gaps. This is when a student clearly notices the limit of their knowledge and is aware of a learning concept that is needed to solve the problem.

Again, the authors do not conclude that the other states in the category positively (or negatively) affect the efficacy of PS-I. The hypothesis on whether these other states are cases for unproductive failure is contentious and should be closely investigated. In truth, the findings of this study indicate that the students barely reached the insufficient and specified knowledge gaps state, while most of their thoughts remained in other pre-AKG-regarded categories, such as sufficient, naïve and uncertain, and insufficient-unspecified knowledge gaps. This finding is not surprising, given that the learners spent most of their problem-solving time assessing the given problem. Even though some learners agonized over the impasse and tried guessing what they needed to know – which the authors considered as starting points of becoming aware of knowledge gaps – most of them did not go beyond this to evaluate their knowledge in those moments or identify errors and reasons for the errors.

This issue can inform the next research question, namely whether each state in the categories leads to productive PS-I. Would students need to be precisely aware of their gaps in order to integrate knowledge and be prepared for the instruction? The authors assume that specific AKG, which learners can experience after agonizing over moments of impasse or explicit or implicit errors (Loibl & Rummel, 2014), would have a better preparatory effect on instruction and bring more beneficial outcomes. The abovementioned study addressed the use of comparing and contrasting activities to specify AKG, however, there still remains room in finding supporting strategies for reaching the AKG state during the problem-solving phase. In this regard, this study suggests classifications, descriptions, and examples of different knowledge states around AKG. This categorization can be utilized as guidance in establishing the directions and boundaries of scaffolding strategies for AKG in future research. Thus, the authors propose follow-up studies that firstly, expand the research scope from the problem-solving phase to the instruction phase to see how different knowledge states around AKG (which is perceived during the problem-solving phase) affect learners' behaviors during the instruction and learning outcomes, and secondly, explore the effects of instructional interventions promoting AKG.

Design Knowledge and Learning Pathway of a Grassroots Innovator

Brandon Reynante, Stanford University, reynante@stanford.edu

Abstract: Many poverty alleviation efforts employ a charity-based approach that re-entrenches inequitable power relations and results in solutions that are inappropriate for the local context. Recently there have been calls to leverage the design knowledge of "grassroots innovators" for sustainable development. I draw upon a five-week ethnographic study to describe the design knowledge and learning pathway of an exemplary grassroots innovator and examine how social norms and power dynamics have shaped their learning opportunities. The findings counter deficit narratives about design and engineering expertise in marginalized groups and contribute to a better understanding of how to support the development of grassroots innovators.

Keywords: indigenous knowledge, learning pathway, engineering, design, social justice

Introduction

In the summer of 2015, I travelled to a rural village in the Philippines as part of an engineering service-learning project. The interdisciplinary project team included two faculty advisors and about half a dozen students from a large public university in the U.S. We had been approached by a Philippines-based non-governmental organization (NGO) that operates across the country to build homes for the homeless and incubate social enterprises to provide jobs for the jobless. The village—built by the NGO—lacked reliable and affordable electricity, forcing many residents to use candles and kerosene as light sources, which is damaging to both human health and the environment and can result in accidental fires. To address this issue, our team had designed a solar street lamp to light up outdoor areas. The NGO hired the village handyman and electrician, Rogelio, to help us construct and install the lamp. He cut and welded the metallic structure, laid the concrete foundation, and soldered the electrical components. At one point in the process, our team spent hours trying to pass electrical wires through the inside of the street lamp pole. Rogelio noticed our struggle and came over with an improvised tool—a piece of stiff wire with a hook on one end—and proceeded to thread the wires through the pole in a matter of minutes.

We left the Philippines hoping that the villagers would replicate our design and install street lamps throughout their village. However, several months later we discovered that the locals were not replicating the street lamp as we had intended because it was too large, complex, and expensive. The community members did not even find the street lamp very useful because it only lit a small portion of their village. Eventually, after eleven months of operation, the lamp malfunctioned due to water damage from the harsh weather conditions, which include frequent typhoons, but the community members did not possess the proper resources to repair it.

Unfortunately, this kind of story is all too common. Many socioeconomic development and poverty alleviation efforts employ a similar type of charity-based approach involving a top-down transfer of resources from donors to beneficiaries without meaningful community involvement, yet this re-entrenches inequitable power relations and results in solutions that are inappropriate for the local context (Nieusma & Riley, 2010). A quote by Paulo Freire, Brazilian social justice educator, frames the issue: "To alienate humans from their own decision-making is to change them into objects," (Freire, 1968). Friere argued that people cannot be liberated from oppression; they must liberate themselves. A more bottom-up approach, known as participatory design, involves expert designers and members of impacted communities working together to create technology-based solutions (Schuler & Namioka, 1993). Participatory design approaches recognize the knowledge held by community members about their local context. However, models of collaboration in participatory design often take a deficit view of community members in relation to design-related knowledge, assuming that there is a need to build their design capacity at the start of the process (e.g., Drain & Sanders, 2019).

Recently, there have been calls to recognize the structural causes of inequities and leverage existing community-based design knowledge, practices, and traditions in addressing them (Costanza-Chock, 2020; Reynante et al., 2017). Individuals from marginalized groups who generate novel, improvised, technology-based solutions to local problems have been referred to as "grassroots innovators" (Campbell, 2017). The practices of grassroots innovators are useful not only for solving local problems, but they might also serve as a way to promote sustainable development on a larger scale if they were supported more broadly (Seyfang & Smith, 2007) and used as a source of inspiration for more sustainable Western engineering and design practices (Hess & Strobel, 2013).

After the street lamp episode, our project team transformed our approach to build our project around Rogelio, who we recognized as a grassroots innovator. Rogelio collaborated with the university students to design and prototype handheld solar lanterns, which are substantially more desirable, affordable, and replicable than the street lamp (see Figure 1). The design of the lanterns leveraged Rogelio's knowledge of mechanical and electrical fabrication and his experience working with locally available and repurposed materials. Rogelio has since taught several of his fellow villagers how to manufacture and repair the lanterns, and they are in use throughout the community.

Figure 1. Handheld solar lantern prototype.

What experiences contributed to Rogelio becoming such an exceptional grassroots innovator? Other members of his village possess similar skills, but not to the same extent, and notably none of them are women. Answering this question may contribute to a better understanding of how to recognize and support the development of grassroots innovators more broadly. I trace Rogelio's long-term learning pathway, describe how his experiences supported the development of particular kinds of knowledge and practices relevant for grassroots innovation, and examine how cultural factors and power dynamics have shaped his learning opportunities.

Conceptual framework and methodology

To explore Rogelio's learning across space and time, I draw upon the Learning Pathways framework (Nasir et al., 2020), which conceptualizes learning as occurring along culturally organized "learning pathways". These pathways are longer-term trajectories of participation in activities that take place across formal and informal learning spaces, are facilitated or constrained by social systems and institutions that differentially position individuals' access to resources and experiences, and are shaped by issues of identity. This framework provides a way to illuminate the structural causes of some of the inequities experienced by grassroots innovators as well as the community-based design knowledge that can be leveraged to address these inequities.

I constructed Rogelio's learning pathway by describing and visualizing key learning activities over time, settings where they take place, the people and resources involved, and salient social identities. This method centers a "wide-angle view" of learning, highlighting the dynamics of learning over weeks, months, and years (Barron et al., 2013). Learning pathways can help map and describe the origins, evolution, and development of engagement in activities over time and how these patterns of sustained activity result in more stable interests and areas of expertise (Barron, 2010).

I collected data during five weeks of ethnographic fieldwork at the rural village in the Philippines in June and July of 2019. Ethnography provides rich, contextual information about the shared cultural patterns of members in a group and is thus appropriate for exploratory research into the design practices and learning pathways of individuals (Creswell, 2013). Rogelio (37 years old at time of observation) is our focal community member since he is an exemplary grassroots innovator. Over the five week period I generated 23 days of field notes, 190 photos, and 159 minutes of video. I also conducted a 45-minute semi-structured interview with Rogelio at the end of the ethnography. During data collection, I focused attention on Rogelio's design skills related to grassroots innovation and his explanations of how he developed those skills. I wrote analytic memos to support interpretation and sensemaking of the data (Emerson et al., 2011). In these memos, I attempted to construct a narrative chronology of Rogelio's relevant experiences, and I subsequently checked these interpretations with Rogelio.

To analyze the data, I used an inductive qualitative analysis approach (Boyatzis, 1998), which consisted of open coding the observation field notes, interview transcript, and analytic memos. I coded the texts for information related to Rogelio's design knowledge and learning pathway. The field notes, interview transcript, and memos were coded simultaneously as a way to triangulate the data and therefore enhance validity (Creswell, 2013). I then conducted thematic analysis by reviewing the coded excerpts to identify patterns (Saldaña, 2015).

A primary limitation of this work is that I am not a member of the community I studied. I have lived my entire life in the U.S., and although I do have Filipino heritage, I did not experience Filipino culture in a deep, meaningful way growing up. I also have an academic background in engineering and education. These identities and experiences position me as a privileged outsider in relation to the community members, and in turn shape my interpretations of results. I attempted to mitigate this issue by foregrounding Rogelio's own voice and consulting with him about the findings to incorporate his input and feedback.

Rogelio's learning pathway

Rogelio was born in 1983 in the Bicol region of the Philippines. He grew up in poverty, unsurprising since the Philippines is a developing country: ~44% of the population lived below the poverty line at the time of Rogelio's birth (Asian Development Bank, 2009). Due to his family's financial constraints, Rogelio often repurposed readily available materials into toys throughout his childhood. This practice of 'bricolage' (Levi-Strauss, 1966) is the "making use of bricoles—the odds and ends, the bits left over, the set of unrelated or oddly related objects... The bricoleur always has a view to what is available, what is at hand" (Harper, 1987, p. 74).

These early habits led Rogelio to become extremely resourceful in his later design work, resulting in highly affordable solutions. Even many of his tools are improvised, including a ladder made from pipes and rebar and a soldering iron holder made from a wood block and pipes (see Figure 2). Other materials I saw him co-opt during my fieldwork included plastic cups, compact discs (CDs), PVC plates and pipes, and a mobile phone USB charger. Upon being asked about this practice during the interview, Rogelio said that, "Some person they throw the garbage, but there's some things we can use. I try to keep it. I store a lot of reuse materials."

Figure 2. Some of Rogelio's improvised tools: (a) ladder; and (b) soldering iron holder.

Readily available materials and tools shape Rogelio's imaginable design space. During one prototyping session, Rogelio looked around at the eclectic assortment of materials lying beside him—including cannibalized components from other prototypes—and held them near his new prototype to visually imagine how they might be repurposed to help him achieve his intended design. Bricolage seems to be a widespread cultural practice throughout the Philippines, as I noticed many improvised structures and vehicles (our language translator referred to this as "Pilipino Ingenuity").

Around the age of 12, Rogelio started drawing cartoons. His father was an architect, and Rogelio thinks that perhaps watching his father draw blueprints imbued him with some innate talent for sketching. Sketching is a key form of communication in design activities (Sanders et al., 2010). After high school, at 18 years old, Rogelio got his first job working as a construction laborer building houses. His duties included mixing cement, laying bricks, bending steel, and installing plumbing. At the age of 20, he spent two years working in a factory assembling consumer products such as bicycles, ovens, and rice cookers.

At 22 years old, Rogelio started along the path to becoming an electrician. He studied electronics and building wiring for 4 months at a vocational school and took a government test administered by the Technical Education and Skills Development Authority (TESDA) to obtain a certification required for working abroad.

Simultaneously, he apprenticed with his brother, an electrician, for one year. Rogelio hated the work at first because it was physically demanding, but eventually he found that it came more easily: “It’s simple when you love your work,” he said. After completing the apprenticeship, Rogelio started working as an electrician. Unfortunately, a few years later there was a violent typhoon that flooded his house and destroyed his high school diploma and TESDA certificates, which have since prevented him from obtaining work abroad.

During his time studying and working as an electrician, Rogelio had been living in a slum. At the age of 28, he got the opportunity to move to a rural village built by a Philippine-based poverty-reduction NGO (the same organization that later partnered with my team on the solar lamps and lanterns). Rogelio’s father had served as the foreman overseeing construction of the village. Rogelio built a bamboo structure next to his house to serve as a garden. The NGO hired Rogelio to be the electrician and handyman for the village and other nearby facilities owned by the NGO, which ran a farm adjacent to the village and supported various social enterprises, many based on products from the farm. The NGO also hired Rogelio’s sister to work as a housekeeper for the residences where volunteers and visitors to the farm stayed. Over the next few years, Rogelio says he became “famous” in the region for his electrician and handyman skills and was often sought out by surrounding communities to fix their electrical and mechanical problems. Rogelio’s identity as an electrician is very salient for him.

Rogelio’s work as a construction laborer, electrician, and handyman furthered his bricolage skills and fostered the development of craft knowledge, including soldering, welding, and manipulating various materials (e.g., metal, plastic, bamboo). Craft knowledge is kinesthetic and intuitive, entailing a deep understanding of the ‘ways’ of many materials—how they respond to attempts to alter their shape and pliability—acquired through tactile, empirical perception (Crawford, 2009; Harper, 1987). One episode revealing Rogelio’s craft knowledge was when he created an improvised flange on a straight PVC pipe’s end, which he learned while apprenticing with his brother (see Figure 3).

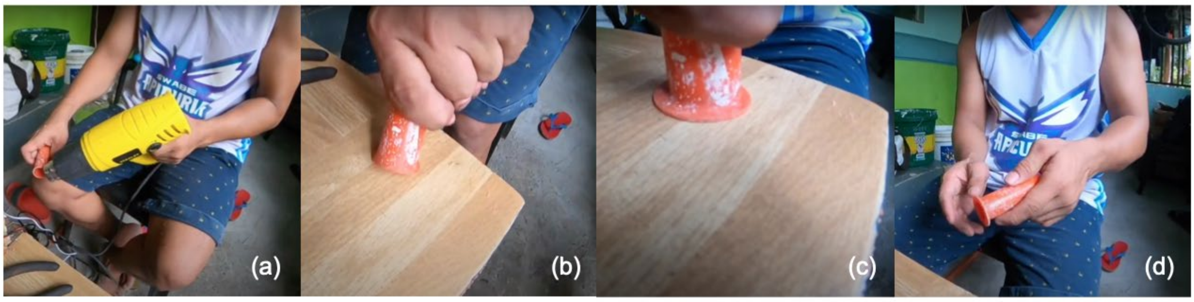

Figure 3. Rogelio’s process of creating an improvised PVC flange: (a) heat one end of a PVC pipe until it becomes malleable; (b) simultaneously press and twist the heated end of the pipe on a flat surface; (c) hold the deformed pipe in place until it cools and hardens; (d) finished product.

Rogelio’s craft knowledge expertise, with its basis in material reality, seems to have led him to develop a preference for creating physical artifacts to support his design thinking and communication. “It’s hard to work without materials at hand,” he said during the interview. At one prototyping session, Rogelio laid components and materials on the table in front of him and held them up next to each other in various combinations to visualize how they might fit together, but soon remarked, “Maybe we make a sample because it’s hard to think which is the best.” During one collaborative design session, a university student co-designer was attempting to verbally explain her design idea to Rogelio, but he was struggling to comprehend and instead stated, “Maybe we need a sample.” Making tangible things is one of the primary forms of communication in design activities (Sanders et al., 2010).

Rogelio also embraces trial-and-error experimentation, learning through iterative testing to progressively refine solutions. Despite his deep craft knowledge, Rogelio occasionally made mistakes, as when he cut off the bottom of a cup of noodles and attempted to drill a hole in it, but the plastic cracked severely. He immediately grabbed another plastic cup of noodles, this time drilling the hole before cutting off the bottom, succeeding. He also made multiple lantern prototypes to improve the design (see Figure 4), saying: “Let’s think about how to make it better. It’s experiment time.” The success of trial-and-error testing in many fields, particularly engineering and design, indicates its value as a general epistemic strategy (Pirtle, 2010).

Figure 4. Various solar lantern prototypes.

When I first visited Rogelio's village in the summer of 2015, he was 33 years old. The mission of the service-learning program is to partner with nonprofit organizations to improve the well-being of underserved communities and provide cross-cultural design experiences for students. It was through a partnership with the NGO that built Rogelio's village that he had the opportunity to join our project. We used Rogelio's existing craft knowledge and bricolage practices as bridges to new content—specifically, interpreting and drawing circuit diagrams for solar energy systems. These are forms of scientific knowledge—mental constructions that are more intellectually tractable than material reality, and in particular amenable to mathematical representation (Crawford, 2009). Rogelio said that it is "very good to know how to do solar," which he learned from the university team. He integrated this new scientific knowledge with his existing craft knowledge and bricolage skills to create a solar lantern made from a repurposed plastic jar, PVC pipe, a solar panel, LEDs, and a battery (see Figure 1).

A couple years after we began working with Rogelio, he tried to start a business making and selling "golden" duck eggs (i.e., eggs soaked in turmeric). The NGO that had built Rogelio's village had provided resources such as funding and physical space to other aspiring entrepreneurs, but they were primarily foreigners or formally educated, wealthy Filipinos. When Rogelio sought assistance from the NGO founder/director (who is also Filipino), his request was denied. Rogelio says he became angry and "got into arguments" with the NGO staff. Simultaneously, our university team decided it would be useful to try and help the local villagers start a business making and selling the handheld solar lanterns to spread light to other communities and provide an additional income source. We identified Rogelio as the most likely candidate for the business leader, but when we approached the NGO director, we discovered he lacked faith that a poor Filipino villager could be a successful entrepreneur. Thus, Rogelio was twice denied the opportunity to learn entrepreneurship skills, and possibly achieve greater financial security for his family. After revealing how his aspirations for entrepreneurship were crushed, Rogelio told me that he hopes to study engineering one day because he dreams about fulfilling a promise to his wife about being able to give her everything she desires.

Key learning activities, settings, resources, people, and social identities are mapped along Rogelio's learning pathway using a timeline representation in Figure 5. This visualization helps highlight patterns of learning activities. I recognize that all of Rogelio's various social identities are intersectional and embedded throughout, but I foreground certain identities that seem particularly germane for a given learning activity.

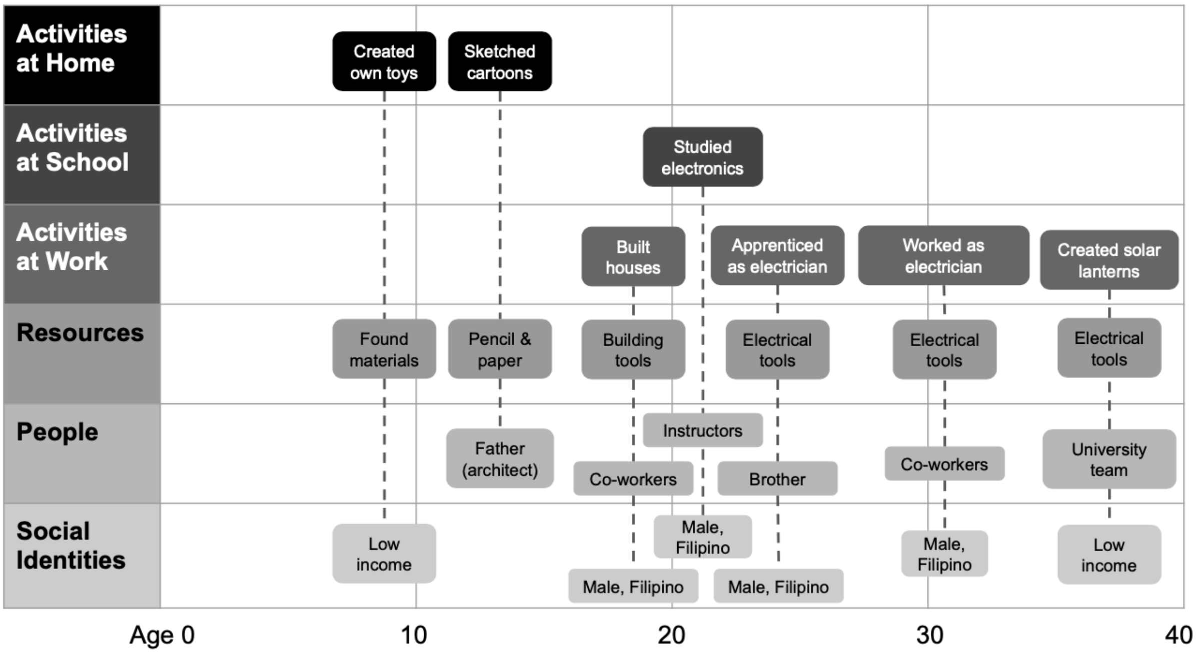

Figure 5. Visualization of Rogelio's learning pathway.

Discussion

This work contributes to growing evidence countering pervasive notions that individuals from low-resource and marginalized communities lack design knowledge (e.g., Blikstein, 2008; Campbell, 2017; Cavallo, 2000). Rogelio learned how to become a grassroots innovator in several ways. He developed much of his craft knowledge by constructing physical artifacts. According to the theory of Constructionism, learning happens particularly well through the process of actively making tangible objects in the real world (Papert, 1980). Apprenticeship also played an important role, as Rogelio said he learned many "tricks of the trade" (e.g., making the improvised PVC flange) by watching and imitating his brother and other co-workers. Learning is often facilitated in this way through legitimate peripheral participation in a community of practice (Lave & Wenger, 1991). Rogelio learned his scientific knowledge through collaboration with the university service-learning team, which supports claims that mutual learning occurs during participatory design activities (Schuler & Namioka, 1993). Formal education seems to have played a minor role, as Rogelio pursued electronics vocational training for only four months and never mentioned other formal educational experiences.

Various institutions and social systems structured access to opportunities and positioned Rogelio along his learning pathway. For example, socio-economic class played an important role. Rogelio has lived in poverty his entire life, and the associated financial and material constraints forced him to create his own toys as a child and his own tools as an adult, thus fostering his bricolage skills. As Plato taught us in the 'Republic', 'our need will be the real creator'. People in socio-economically developing contexts have always been driven to improvise and innovate due to inequality, poverty, and unmet needs (Campbell, 2017). Rogelio's nationality and gender also played a key role in his learning pathway. The development of his craft knowledge was supported by access to men who served as role models and sources of learning: his father, an architect and construction foreman; his brother, an electrician; and various other male co-workers. Access to these people and associated learning experiences positioned Rogelio as capable, and he began to develop an identity as a grassroots innovator. This positioning was enabled by social norms in the Philippines, since jobs like construction worker and electrician are considered acceptable for men, but not women (Asian Development Bank, 2013). If Rogelio were a woman, he may have instead become a housekeeper like his sister. Furthermore, the intersectionality of Rogelio's ethnicity and class enabled him to gain scientific knowledge through his partnership with the university team, since we were seeking to work with low-income communities, but it hindered his opportunities to gain entrepreneurship skills. The director of the partner NGO doubts that poor Filipinos can be successful entrepreneurs. Many NGOs ostensibly support poverty alleviation, but they can also obstruct by operating in a way counter to community self-determination (Del Gaudio et al., 2016). There is often a power differential between poverty-alleviation organizations and their beneficiaries, and this imbalance is exacerbated through charity-based approaches (Nieusma & Riley, 2010). As the results of this study demonstrate, other individuals or organizations have the potential to reduce such power asymmetries by leveraging their own privilege to serve as allies by positioning marginalized individuals as knowledgeable and capable designers.

For those seeking to identify grassroots innovators, it is important to recognize that all members of marginalized groups have useful knowledge based on cultural practices (Moll et al., 1992). For example, bricolage seems to be a widespread cultural practice throughout the Philippines. One way to support grassroots innovators is to create Constructionist learning environments that center their indigenous skills and resources to support learning about and through technology. Our team leveraged Rogelio's existing craft knowledge and bricolage practices to engage him in creating solar energy systems. Other researchers have successfully used this approach in other developing countries such as Thailand (Cavallo, 2000) and Brazil (Blikstein, 2008). However, to avoid re-entrenching power asymmetries between researchers and members of non-dominant communities, it is important to take a participatory approach by involving grassroots innovators as co-designers of learning experiences (Bang & Vossoughi, 2016) and of new technologies and infrastructures that support knowledge production (Gutierrez et al., 2020).

Another way to support grassroots innovators is to mirror their advances by legitimizing their knowledge as valuable. Historically, making and tinkering were core components of engineering, but in the second half of the 20th century there was a push towards mathematization and scientization (Blikstein, 2013). Nowadays, engineers are not expected to do manual labor, only to define the details for an artifact to be made by someone else (Pawley, 2012). The primacy of math and science within contemporary conceptions of engineering serves to exclude non-Western ways of knowing (Hess & Strobel, 2013) and can alienate learners who hold more embodied and experimental funds of knowledge (Smith & Lucena, 2016). Rogelio does not consider himself to be an engineer, yet even if he did, would the engineering field—or society at large—allow him to claim this identity? Some scholars have argued for valuing a plurality of epistemologies in science (Medin & Bang, 2014) and computer programming (Turkle & Papert, 1990), and the same is needed in engineering. In particular, bricolage is posed as an equal-status alternative to the abstract analytical methodology of Western science (Levi-Strauss, 1966; Turkle & Papert, 1990). Broadening the definition of *what* counts as engineering and *who* counts as an engineer would imbue grassroots innovators with much needed cultural capital and allow them to develop a sense of engineering agency while affirmatively foregrounding historically marginalized ways of knowing and doing that may be vital in solving the pressing problems of sustainable development.

Cross-Sectional Study of Students' Molecular Explanations of Inheritance Patterns

Moraima Castro-Faix, Rutgers University, moraimac@rutgers.edu
Ravit Golan Duncan, Rutgers University, ravit.duncan@gse.rutgers.edu

Abstract: Genetics is an important topic in the biology curriculum of many countries. Learning genetics is difficult because it involves the need to reason about complex ideas and to link between mechanisms that occur at different levels of organization. Previous research in genetics education has studied either students' understanding of inheritance patterns or their understandings of molecular genetics; very few studies have examined students' understanding of the connection between these ideas. To address this gap, we conducted a cross-sectional interview study with students from middle school to high school, as well as undergraduate and graduate students, after they had experienced "status-quo" instruction in genetics. We analyzed student responses and described the molecular mechanistic explanations students used to explain inheritance patterns. Our findings allowed us to propose a progression describing the gradual use of genetics ideas. We discuss the implications of the tentative progression for instruction aimed at supporting reasoning in genetics.

Introduction

Discoveries originating from genetics research are increasingly becoming part of our daily lives. These include the discovery of gene editing, the availability of genetic testing (e.g., 23andMe), GMO-based products in grocery stores, increased prenatal testing, and the use of novel therapies for cancer treatment (Boerwinkel, Yarden & Waarlo, 2017; Gericke & Smith, 2014). For instance, the company 23andMe provides genetic testing to the public without consultation with a genetic counselor to help the consumer interpret the results of the tests (23andMe, 2020). This may be problematic for individuals who may not have a full grasp of genetics or have difficulties understanding the probability of developing a genetic disorder. These interpretations of genetic screens may cause anxiety in the consumer or possibly influence important medical decisions, like deciding whether to have breast cancer screenings or prenatal testing (Bellcross, Page, & Meaney-Delman, 2012; Hawkins & Ho, 2012). Additionally, the discovery of CRISPR by Emmanuelle Charpentier and Jennifer Doudna, and their recent winning of the Nobel Prize, has led to important ethical discussions about the role these discoveries have in society and the possibility of genetically modifying human embryos to prevent inherited diseases (Weisbverg, Badagio & Chatterjee, 2017).

Yet, high school graduates and college students often have difficulties comprehending these scientific advances, which can make it difficult to engage with the civic, personal and ethical issues they may encounter stemming from genetics advances (Stern & Kampurorakis, 2017). Stewart, Cartier and Passmore (2005) proposed that genetics literacy consists of understanding three models of genetics. These models include: (a) the inheritance model, which explains patterns of inheritance (e.g. recessive, dominant, sex-linked) and the understanding of how alleles (gene variants) are transmitted across generations; (b) the meiotic model, which involves the physical transfer of genes from one generation to the next through sex cells; and (c) the molecular model, which includes the cellular and molecular mechanisms by which genes bring about traits. This model involves the understanding that genes code for proteins and that changes (mutations) in the recipe (DNA) may lead to changes in the structure and function of proteins. Moreover, genetics literacy involves the linkages among these models along with understanding the role of the environment (Duncan, Rogat & Yarden, 2009; Stewart et al., 2005).

To help students become literate in genetics, it is important to facilitate student understanding of the connection between molecular and the inheritance models as making connections can help students understand the underlying molecular mechanisms involved in the expression of traits (Haskel-Ittah & Yarden, 2019; Marbach-Ad & Stavy 2000). For example, in muscular dystrophy there are two main types of mutations in the dystrophin protein a complete loss-of- function of the dystrophin protein or the production of a misshapen protein that is still partially functional. Duchenne muscular dystrophy (DMD) is the most common type of this disorder and consists of a loss-of-function mutation in the dystrophin gene (Falzarano et al., 2015). The second most common type for this disorder is Becker muscular dystrophy. This type of muscular dystrophy has a milder effect than Duchenne because in Becker's muscular dystrophy the dystrophin protein has structural problems that cause it to have an altered form (Falzarano et al., 2015). However, the protein can partially function to allow for the formation of muscle cells. These disorders may originate through mutations in early development or be inherited.

Regardless of the type of inheritance the problem with the muscle cells are caused by mutations in the genes that code for proteins involved in making muscle cells. Understanding how it is possible that a disorder like muscular dystrophy can have different forms, and origins involves understanding the link between classical and molecular genetics. However, the linking of these models is one of the areas of most difficulty for students because it involves understanding the mechanisms that occur at different levels of organization consisting of understanding what happens at the molecular, cellular and organismal level (Duncan, 2007; Todd & Romine, 2017). Few studies have examined how students form these connections and none have taken a cross-sectional approach (Todd & Romine, 2017; Wolyak, 2013).Therefore, we know little about how such understandings develop over the secondary and undergraduate levels. To address this gap, we conducted a cross-sectional interview study with students from middle school and high school, as well as undergraduate and graduate students, after they had experienced "status-quo" instruction in genetics. Our aims for this work were to (a) characterize the kinds of explanations students use to provide the link between inheritance patterns (recessive or dominant) with the underlying molecular mechanisms, and (b) characterize how these explanations change over the course of schooling.

We developed qualitative analyses of cross-sectional data with the purpose of identifying and characterizing the ways the students in each grade developed molecular explanations of inheritance patterns. The following research questions guided our analyses: 1) What kinds of molecular explanations can students provide for inheritance patterns? , and 2) How does the use of these explanations change over the course of schooling? We next describe the theoretical frameworks that informed our research questions.

Theoretical framework: Framework of genetics literacy and a normative model of genetics

To characterize the explanations that students used, we drew on the framework of genetics literacy by Stewart, Cartier and Passmore (2005) to identify core genetics ideas, and on a normative model of genetics that consisted of Muller's 1932 definition of mutation as the *loss or gain* of function of a protein (Wilkie, 1994). This definition is still widely used by scientists and textbooks to describe the effects of mutation in protein function (Griffiths et al., 2005; Zhou et al, 2020). Together these two frameworks allowed us to identify and characterize the ideas students were using to reason about molecular mechanisms involved in the expression of phenotypes, such as how a gene for albinism brings about observed physical differences in skin and hair color.

The framework of genetics literacy allowed us to classify and identify the ideas that belonged to the inheritance and the molecular model (Stewart et al., 2005). For example, ideas around inheritance patterns and the connection genes and proteins and we then analyzed the ways the students developed molecular explanations for inheritance patterns.

The normative model of genetics allowed is to identify and classify the mechanisms that the students developed to reason about inheritance patterns. Muller's 1932 model describes how scientists reason about mutations and their effects in protein function. Mutations can be classified as *loss of function* or *gain of function* (Muller, 1932). In *loss of function* mutations there may be either a complete loss of the protein or a reduction of the protein function, which can result in disease. For instance, in sickle-cell anemia the hemoglobin protein is affected by a mutation that causes a change in structure (Pauling, Itano, Singer & Wells, 1949). Normally, hemoglobin is a protein that transports oxygen that is located on the cytoplasm of red-blood cells. In the mutated form, the hemoglobin has a different shape and is less efficient at transporting oxygen. As a consequence, the lack of oxygen causes the red blood cell to become "sickled". This causes the cells to stick together and have difficulties moving through the blood vessels (Hopkins, 2020; Pauling et al., 1949). Loss of function mutation is usually the mechanism involved in recessive disorders and in some dominant disorders depending on how the mutation is affecting the individual. In contrast, gain of function mutations can lead to an increase in protein expression (more protein is being produced than what is needed), a protein that interferes with the function of another or the gain of a new function. For example, in Hungtinton's disease there is a mutation in the sequence of DNA that produces a protein that is much longer than normal (Bates, 2005). This protein is then cut into fragments ("toxic proteins") that bind to each other and accumulate in neurons, affecting the normal functions of the cells. Gain of function mutations are more often related to dominant disorders (Jones & Hughes, 2011). Therefore, the normative model allowed us to identify if students were able to develop loss and gain of function explanations of inheritance patterns. Our analysis characterizes the different ways students reasoned about classical genetics and molecular genetics and about problems that involved integrating knowledge from both models. We describe a progression of mechanism exhibited across several grades (middle school to graduate students). Findings from this study provide evidence about how students make links among the genetics models and contributes to the limited research base on genetics literacy.

Methods

Study context and participants

The aim of this study was to understand the kinds of explanations that students provided to connect the classical and molecular models of inheritance. We gathered cross-sectional interview data from students at different levels and expertise in genetics. We interviewed students from the following groups: 15 students in middle school (MS), 81 11th-grade biology students, 15 high school biology advance placement students (AP), 31 undergraduates and 12 graduate students that had completed coursework in genetics. Prior to the interview we made sure that the students in each group completed status-quo instruction in genetics and participated in the genetics units or courses that were appropriate to their grade level. For instance, the high school students completed lessons on the structure and function of proteins and their relationship to genes, and they also learned about inheritance patterns. The high school (AP and 11th grade students) and middle school students that participated were from two districts. District 1 consisted of a diverse suburban school with the following demographics: 40% African American, 30% Hispanic, 17% Asian and 13% Caucasian with 50% of the students eligible for free or reduced-fee lunch. District 2 consisted of a suburban school with the following demographics: 55% Caucasian, 35% Asian, 4% African American and 6% Hispanic with 15% of the students eligible for free or reduced-fee lunch. The university students (graduate and undergraduate students) were from a large diverse north-eastern university with the following demographic: 39.8% White, 23.3% Asian, 12.2% Hispanic or Latino, 7.82% Black or African American, 2.79% Two or More Races, 0.212% Native Hawaiian or Other Pacific Islanders, and 0.0605% American Indian or Alaska Native.

Data collection

We collected individual interview data from each student. The interviews lasted 45-60 minutes and consisted of open-ended tasks modified from a previous studies (Castro-Faix, Duncan & Choi, 2020; Duncan, Choi, Castro-Faix & Cavera, 2017). In the first task, the students were asked to reason about the molecular mechanisms for the inheritance of a hypothetical recessive disorder that we called blood-clotting disorder (BCD). The students were given a pedigree that showed the recessive trait “skipping” a generation and they were asked about the genes and traits of th0e individuals shown in the pedigree. The goal of this first task was to evaluate student understanding of inheritance patterns, the role of sex cells in inheritance, and the molecular basis of genetic traits. In the second task, the students were asked to reason about two hypothetical disorders, one dominant and one recessive. In the case of the dominant disorder, the patient is heterozygous for the disorder (Bb). The individual inherited a ‘b’ copy that codes for the “normal” protein and a ‘B’ mutated allele that codes for a mutated protein that does not work properly. In the case of the heterozygous recessive disorder (Aa), the individual inherited an ‘A’ copy that codes for the “normal” protein and an ‘a’ allele that codes for a mutated protein that does not work properly. We then asked students to explain how a heterozygous genotype can result in a healthy individual (Aa – recessive disorder) and a sick individual (Bb – dominant disorder). The purpose of this task was to elicit molecular explanations for the disease and to figure out how they would explain each disorder. In the third task, students were given 16 cards listing genetics terms like: cell, alleles, chromosomes, DNA, proteins, recessive, *etc*. The students were then asked to arrange the cards in a concept web and draw arrows that linked the terms (as many as they could). The concept web was used to encourage the participants to organize their ideas and explain the terms and the relationships they noted among the terms (Butler-Kisber & Poldma, 2010). In this task, our goal was to emphasize the relationship between alleles and proteins, and to observe how the students elaborated on this relationship.

Data Analysis

Each task was then analyzed qualitatively to determine what kinds of molecular explanations students provided for the inheritance patterns of trait; that is, all three tasks were analyzed using a directed content analysis approach with the purpose of identifying and examining how students integrated ideas from the molecular and inheritance model of genetics ideas (Chi, 1997; Hsieh & Shannon, 2005; Mayring, 2000) and used these ideas to develop molecular mechanistic explanations of inheritance patterns. According to Hsieh and Shannon (2005), the goal of this approach is to inform an existing conceptual framework or theory. The existing theory focuses the research questions that are going to be studied and provides direction about the variables to be studied (Hseih & Shannon, 2005). We used Stewart et al.’s (2005) model of genetics literacy to focus our research questions. The framework provided the initial coding scheme and the relationships between the codes that were used to identify the molecular mechanisms that students used. Moreover, we aimed to characterize their ideas using a normative model of genetics that we previously described (Muller, 1934). This model allowed us to classify students responses into gain and loss of function mutations and to figure out if the students were using the molecular mechanisms previously discussed.

Results

Our results consist of two main findings: (a) we identified several mechanisms students used to connect the molecular and inheritance models, and (b) we characterized a progression (based on cross-sectional data) that describes the kinds of mechanisms students provided to connect the inheritance and molecular models.

What kinds of explanations do students provide to connect these two models?

We first analyzed the molecular mechanisms students were using to explain inheritance patterns. Table 1 shows the mechanisms students used to explain dominant and recessive disorders. The first column illustrates the molecular mechanisms we identified and how they map onto the normative model of genetics. The second column provides an example of students' statements for each context (e.g. dominant or recessive). Our findings indicate that students across all grades (see Table 1, Table 2) developed *loss and gain* of function explanations to explain why the heterozygote (Aa) is sick in a dominant disorder and healthy in a recessive disorder. We will discuss these in greater detail below. In the next section we will discuss each molecular mechanism and how it relates to the respective inheritance pattern.

Recessive disorder

In the context of the recessive disorder, the students were given a pedigree of a recessive disorder and were asked to explain how this disorder was inherited and to explain the molecular mechanisms that caused the heterozygote individual to be healthy. We found that the students invoked the mechanisms of c*ompensation* and *silencing* to explain why a heterozygote (Aa) individual is healthy in a recessive disorder. The following, quote from a middle-school student illustrates the use of the *compensation* mechanism. "The recessive genes have mutations, but the dominant genes make up for it because they make enough protein and that's why the carrier (Aa) is healthy". Students from all the groups, middle school (50%) to graduate school (100%), explained how the dominant allele was *"compensating*" or was producing enough protein to ensure that the heterozygote individual was healthy. That is, they seemed to understand that the dominant allele as being able to complete the function without the recessive allele. Similarly, 10% of the high schoolers, 15% of the AP students and 30% of the undergraduate students operationalized this explanation of compensation with a mechanism of *silencing* that involved the assumption that the recessive allele is non-functional. In this case, the recessive allele is being turned off or being *silenced* by mutations, therefore they assumed that a mutation can cause cells to turn off the expression of the recessive allele. For example, in the following quote, a high school student describes the recessive allele being silenced. "It could be that the gene is somehow mutated, and that gene expression of that gene is turned off. The recessive allele cannot be transcribed. You can't make any proteins from that gene". This is interesting, while not entirely accurate, because it shows that students at the high school level can understand that the silencing of genes can occur. In the next section we discuss how the students reasoned about dominant disorder.

Table 1: Molecular mechanisms that students used to explain the dominant and recessive patterns of inheritance

Molecular Mechanism	Student Example
1.*Loss-of-function* ***Compensation*** -the proteins made by the dominant allele is sufficient to allow the cell to function normally therefore the allele can compensate for the recessive. Inheritance Pattern: Recesive	"The "normal" proteins compensate for the protein that isn't working the DNA that they inherited from the parent that has the big "A" is "enough" to complete the function of the protein. The protein will be enough to carry on the function even if half of the protein is missing"

2. *Loss-of-function* ***Silencing*** Mutations can turn genes off. Inheritance Pattern: Recessive and Dominant	*Recessive:* "In that case just the dominant one, the amino acid that codes for whatever this has, it's going to exhibit only the dominant ones whereas the ones with the (r) are going to be kind of quiet. They're not going to be as active. I wouldn't say the (r) is making anything. I would say the (R) is making everything. I think the (r) is just there to pass down to the offspring." *Dominant:* "Well, sometimes in dominant disorders you might have proteins not working properly. I think in this case, is because he doesn't have enough healthy protein, and this can be caused by low transcription like problems with a promoter or a receptor not being able to initiate the particular protein to be made."
3.*Loss-of-function* ***Haploinsufficiency*** The dominant allele doesn't make enough. Inheritance Pattern: Dominant	"The big R is directions to make that protein, but the little r doesn't make anything, hypothetically. Then somebody with two big Rs would make ... they would have that instruction from both of their big Rs but somebody with a big R and a little r they would ... they would make the protein because of their big R, but maybe not to the same amount because they don't have two big Rs. The little "r" is not making enough protein, but the dominant allele makes enough."
4. *Gain-of-function* ***Dominant-Negative Mutations*** The protein interferes with the function. Inheritance Pattern: Dominant	"The heterozygote is sick because the mutated protein has something wrong in the structure that allows it to it bind to the healthy protein forming dimers and interferes with the function possibly by blocking it's active site."

Dominant disorder

In this context the students were given two multiple-choice questions that asked students to explain why a heterozygote (Aa) individual is sick in a dominant disorder. We found that students used the mechanisms of *haploinsufficiency*, *dominant-negative mutations* and *silencing* to explain why the heterozygote (Aa) individual is affected by the disorder (Table 2, row 3). *Haploinsufficiency* occurs when one allele in the pair of alleles is mutated causing a decrease in the total production of a protein. The use of this explanation suggests that students understood that the "healthy" allele is not able to produce enough protein for the individual to have a "normal" phenotype. For example, in the following quote a high school student states that "Sam" is not healthy because having one healthy allele "a" is not enough for him to be healthy. "Sam is not making enough protein to be healthy. He has one dominant(A) and one recessive allele(a). The recessive is the correct one , this allows him to make the Tropin but he doesn't make it in the quantities that he needs. He is missing one healthy allele therefore he doesn't make enough of the protein because of the mutation in the A allele."

Dominant negative mutation explanations were used to explain dominant disorders by 10% of the high school students, 20% of the AP students, 35% of the undergraduates and of the 90% of the graduate students. In this explanation, the students suggest that the mutated protein is somehow inhibiting the function of the healthy allele, therefore the heterozygote individual (Aa) is sick in a dominant disorder (Table 2, row 4). In the following quote, an undergraduate student explains that there may be a mutated protein interfering with the function of the normal protein. "The heterozygote is sick because the mutated protein has something wrong in the structure that makes it bind to the healthy protein and interferes with the function". The use of this mechanism suggests that students understood that proteins can interact with one another, sometimes leading to inhibition of their function.

Silencing in the context of the dominant disorder was used mainly by undergraduate and graduate students and it consisted of mutations that affect the activation of genes, therefore there was a lack of protein expression. For example, in the following quote a graduate student suggests that a gene is being silenced due to mutations. "Sam may be sick for several reasons. However, it is possible that regions that are related to gene activation were affected by the mutation therefore Sam is unable to make the protein he needs to be healthy."

In the next section we discuss how these explanations were developed by students across several levels of expertise.

Development of molecular explanations over time

Table 2 shows the frequencies of types of mechanistic explanations used by each group of students to explain recessive and dominant disorders. The data seems to indicate several interesting patterns. First, some mechanisms are observed with an increase in their use corresponding to education level (e.g., Table 2, rows 1-2). For example, the *compensation* explanation was used correctly by students across several grades to explain the inheritance of recessive and dominant disorders. Similarly, constructing *dominant-negative* explanations was challenging, but within reach, for high school students. All of the students used these in the correct context and situation. Second, the mechanism of "*silencing*" in the context of the recessive disorder was not used by middle school students, but it was used by high school students, AP students and very few graduate students. This mechanism was used in a non-normative way by the younger students while the graduate students provided more detail about how a gene can be "silenced. Additionally, silencing was used in the context of the dominant disorder by undergraduate and graduate students, including more detail on how the gene may have been inactivated and how this inactivation can lead to disease. Third, the *haploinsufficiency* explanation, in terms of the dominant allele and the dominant-negative mutations, were used in an appropriate context for the dominant disorder - mostly by graduate students (Table 2, rows 4).

Table 2: Progression of molecular explanations over time

Molecular Mechanism	Inheritance Pattern	MS	HS	AP	College	Grad
1. Compensation--the proteins made by the dominant allele is sufficient to allow the cell to function normally therefore the allele can compensate for the recessive.	Recessive	50%	70%	80%	100%	100%
2. Silencing-Mutations can turn genes off.	Recessive	0%	10%	15%	30%	50%
	Dominant	0%	0%	0%	20%	60%
3. Haploinsufficiency-the proteins made by the dominant allele is not sufficient to allow the cell to function normally.	Dominant	20%	35%	40%	50%	100%
4. Dominant Negative- the protein produced by the mutated allele interferes with the function of the "normal" protein.	Dominant	0%	10%	20%	35%	90%

Discussion and instructional implications

Genetics is an important, but challenging, subject for students to learn and understand. According to Stewart et al. (2005), a literate individual understands the links among the classical, molecular and meiotic models of genetic inheritance. There is little research to show how students integrate these models. Our findings characterize the different mechanisms that students used to link classical and molecular patterns of inheritance post status-quo instruction. The molecular explanations that students developed were, for the most part, consistent with the normative model of *loss and gain of function*. For example, the mechanism of *haploinsufficiency* involves the loss of part of the protein function leading to a decrease in the protein's expression, and the mechanism of *compensation* involves the understanding that although there may be a decrease in the protein's expression the other allele is able to compensate. Our findings indicate that middle school students were able to reason about these ideas of *compensation* and *haploinsufficiency*. These ideas involve an understanding that alleles can code for *enough* protein to complete a function and may suggest a molecular understanding of *dosage* (Duncan, 2017). Understanding *dosage* may allow allows students to traverse several levels of organization because it allows them to understand the relationships among alleles, protein and their physical effects. Helping students understand the relationships between genes and how they bring about their effects is conductive to understanding the mechanistic linkages between molecular and classical genetics (Haskel-Ittah & Yarden, 2019).

Our findings also show that students at the high school level can understand that genes can be turned *on or off.* This idea of *silencing* is critical in the understanding that genes are dynamic entities that are influenced by the environment. Authors, 2020 studied how undergraduates understood phenotypic plasticity, that is how organisms respond to changes in the environment. They found two types of mechanistic accounts: (a) the organism is passively responding to environmental changes, and (b) the organism senses and responds to the environment. Our findings seem to support the idea that understanding how organisms respond is difficult and we propose that understanding that genes can be turned on and off is an important part of conceptualizing how the environment influences gene expression. This is an important idea because understanding that genes are dynamic entities can decrease genetic determinism (Donovan, 2016). Moreover, Duncan, 2007 studied how students understood how plants responded (by ripening) to an environmental change (exposure to ethylene). She found that students that were not able to operationalize a gene expression (or silencing) schema were not able to understand or explain how the organism reacted to the environment or further explain how genes are regulated. Therefore, the understanding that genes can be turned on and off is an important idea for the understanding of gene expression (Duncan, 2007; Haskel-Ittah et al., 2020).

To conclude, we wish to discuss the progression of mechanism use. From these findings we have begun to identify a progression that captures the mechanisms that students used when reasoning about classical and molecular genetics. Duncan, Rogat and Yarden (2009) proposed a learning progression for the integration of molecular and classical ideas. Our findings support the progression and provide details about how students' reasoning about the linkage between molecular and classical genetics may develop over time. Duncan et al.'s (2009) learning progression describes the development of students understanding of eight genetics ideas (constructs) over time (middle school to high school).

Our findings, can begin to specify where instruction can focus to help students develop the mechanistic explanations for the link between molecular and classical genetics, for instance we have shown that instruction should focus on emphasizing that alleles code for proteins and that recessive and dominant are simply categorical to indicate the phenotypic effect of the proteins they code for and that these proteins they are structurally different due to changes in the sequence (recipe). Moreover, instruction should emphasize that proteins have distinct functions that have a direct result in the organism's physical traits. Understanding the connections among genes, proteins, and traits entails reasoning across multiple levels of organization (e.g., sub-cellular, cellular, and organismal levels), a conceptually challenging task since students need to understand the role each level of organization plays in inheritance phenomena and how biological mechanisms at each level relate to each other (Marbach-Ad & Stavy, 2000). Duncan and Tseng, 2011 argue that understanding the link between genes and traits can help students develop a framework for reasoning about complex systems (such as the interaction between classical and molecular genetics) that can be further developed when students understand how physical and cellular phenomena emerge from protein function. Therefore, helping students understand the relationship between genes and proteins can help elucidate the link between the two models.
Similarly, we have shown that helping students understand that genes can be regulated is important but difficult idea, therefore instruction should aim to help students understand that genes are dynamic entities that respond to the environmental changes the organism is interacting with. More studies need to be done to further understand how students reason about these ideas. This article begins to provide evidence about the ways that students link classical and molecular genetics.

Abstract: Argument critique is an important part of scientific argumentation. This paper explores the affordances of a tool for critiquing classroom arguments in science, the Critical Questions Model of Argument Assessment, and how it benefited students with low English Language Arts (ELA) scores, including English Learners (ELs). Critical questions (CQs) evaluate the strength of scientific arguments. This paper presents a comparative case study of how middle-school science students used CQs in two classrooms with high numbers of students with low ELA scores. We found that asking CQs helped students elaborate their thinking and writing and appropriate argument-related terms. Student confidence for engaging in argument critique grew over the course of the school year. The practice of using peer critique with CQs may have the added benefit of differentiating instruction in schools with high EL populations. Overall, the CQs helped to scaffold more complex student discourse among students with low ELA scores.

Keywords: Argumentation, Science Education, English Learners, Critical Thinking

Student oral and written discourse is a key component of reform-oriented approaches to teaching science for understanding (Chen et al., 2016; Sampson & Grooms, 2010). Through discourse, students need to grapple and critique alternative models of phenomena, including their own prior conceptions (Hunt & Minstrell, 1994). Given the centrality of discourse, to what degree can English Learners (ELs) and students with low English Language Arts (ELA) test scores participate in and benefit from this sort of dialogic science instruction? Rosebery et al. (1992) found EL middle school students were quite capable of appropriating scientific discourse, specifically making and testing elaborated hypotheses, when allowed to investigate phenomena related to ecosystems over the course of a year. Likewise, Suárez and Otero (2014) found that third-grade students could engage in scientific argumentation when the instruction was based on explaining tangible, physical phenomena (i.e., guitar sounds) that leveraged their everyday knowledge and terminology.

Beyond these findings, this paper explores a relatively new tool for enabling middle school students to engage in scientific argumentation in general and argument critique in particular, the Critical Questions Model of Argument Assessment (CQMAA; Dove & Nussbaum, 2018). Somewhat unexpectedly, we found that this tool could be particularly beneficial for students with low ELA test scores, many of whom were ELs. This paper presents a qualitative, cross-case analysis exploring some of the affordances of the CQMAA for enabling students who may struggle with language skills to participate in argumentative discourse. The paper is grounded in two conceptual frameworks: (1) a philosophic framework supporting the centrality of critical questions to scientific inquiry, and (2) a pedagogical framework providing some guidance on how ELs and students with low ELA scores can learn to productively use critical questions.

The critical questions model of argument assessment

Critical questions are somewhat standard questions that should be asked to evaluate an argument. As Walton (1996), Verheij (2003), and other philosophers have shown, there are various types of arguments, known as argument schemes, and attached to each scheme is a set of critical questions (CQs) that should be asked to evaluate an argument of that type. For example, in evaluating an argument based on a logical or scientific analogy, one should ask whether there are important differences between the two things being compared. An affirmative answer would weaken the argument, whereas a negative answer would strengthen it. These assessments can be made dialogically, through discussion. However, we have found—based on personal experience—that it is difficult to teach students to recognize the presence of schemes in ordinary discourse, both because of the large number of possible schemes, and because informal arguments do not always exactly fit nicely into the idealized structures of these schemes. We noticed, however, that there are similarities among many of the critical questions for different schemes, and based on this, identified a number of CQs that could be asked about most arguments. These CQs constitute the CQMAA for scientific arguments; there is a slightly different set for practical and policy arguments.

Table 1: CQMAA critical questions for scientific argumentation4

Number	Critical Questions
1.Structure	Is there an argument here? Can I underline the claim? Can I add a star to the evidence? Can I bracket the reasoning?
2.Evidence	Is there evidence? How good is the evidence?
3.Reasons	Are any of the reasons untrue or incorrect?
4.Accurate	Does the argument use or connect with accepted scientific principles?
5.Coherence/ Reasoning	Do the parts of the argument make a path you can follow or are there missing steps?
6.Alternatives	Are there other claims or conclusions that also fit the evidence? Can you rule out other or competing claims or conclusions?
7.Completeness	What is missing or weak in the argument?

As shown by CQ1, the CQMAA is meant to supplement the widely used claim-evidence-reasoning (CER) model of scientific argumentation first proposed by McNeil and Krajcik (2007). The CER model specifies three argument components: the claim (or conclusion), the evidence, and reasoning that connects the evidence to the claim. The CQMAA can be used to improve a student's CER argument. (The CQMAA could also be used with other argumentation models, such as the six-part Toulmin model, 1958, but the wording of CQ1 would need to be slightly altered.) The CQMAA can also be supplemented with more scheme-specific questions. For example, the second set of CQs, relating to evidence, could be supplemented with more specific questions regarding the clarity and reliability of the evidence (see Pluta et al., 2011). A number of science educators, such as Erduran et al. (2004), have called for supplementing the CER model with counterarguments and rebuttals, as these are key components of scientific discourse about alternative models, and the CQMAA is one attempt to meet this call.

For example, consider the phenomenon of lunar phases. Many students believe that the Moon's phases are caused by shadows cast by the Earth (Brunsell & Marcks, 2007). As evidence, students might cite a video showing how celestial bodies block sunlight during an eclipse, reasoning that because the Moon orbits the Earth, at some point the Earth will block the light falling on the Moon. Using the CQMAA, this CER argument could be critiqued based on the quality of the evidence ("It's about eclipses, not lunar phases"), missing steps ("Why and how often does the Earth block the Sun's light and why doesn't this result in an eclipse?"), and the presence of alternative models (i.e., lunar phases caused by the position of the Moon relative to the Sun). Based on a discussion of these issues, students could improve their understanding of the cause of lunar phases.

It should be noted that the CQMAA is a flexible framework; questions can be reworded if necessary to make them more understandable to students or more appropriate to the subject matter. Also, except for CQ1, the questions can be asked in any order, and not all the questions need to be asked.

The pedagogical framework

The CQMAA is intended to be used to support a form of oral discourse known as *collaborative argumentation* (Andriessen et al., 2003), in which students work together to construct and critique arguments. Collaborative argumentation has been found to promote deeper engagement and understanding of scientific concepts (Alexopoulou & Driver, 1996; Asterhan & Schwarz, 2007). Nussbaum and Edwards (2011) examined the use of a graphic organizer known as the Argumentation Vee Diagram containing CQs related to policy issues. They found that during collaborative argumentation that was preceded and followed by completion of an AVD, some ELs appropriated specific CQs and used them spontaneously during oral and written discourse (see also Nussbaum, 2003). The majority of ELs, however, needed the structure provided by the graphic organizer to ask these questions. Likewise, Liu and Stapleton (2020) collected data suggesting that among sixth-grade students, use of graphic organizers and other structured forms of instruction, such as five-paragraph essays, were important to enable ELs to generate written counterarguments.

Our pedagogical framework is rooted in the work of Vygotsky (Wink & Putney, 2004), particularly the notion of scaffolding (Wood et al., 1974) and the internalization or appropriation of social speech (see also work by Anderson et al., 2001). We recognize, however, that the pedagogical framework is incomplete, given the paucity of prior research conducted on how ELs and other students with low ELA scores learn scientific argumentation at the primary (Liu & Stapleton, 2020) and secondary levels (Nussbaum & Edwards, 2011). One purpose of the qualitative research described below is to add to our knowledge of this issue, based on a one-year professional learning (PL) program for secondary teachers, known as Argumentation and Learning for Secondary Science.

Methods

The PL program consisted of a phenomenon-driven 10-day summer institute where teachers used collaborative argumentation while investigating alternative predictions and explanations about phenomena related to force and motion. Participants also completed various graphic organizers individually and in small groups, including an *Argument Analysis Mapping Tool*, where participants generated claim-evidence reasoning (CER) argument components in the left column and then answered CQs from Table 1 in the right column. They also used model-evidence link (MEL) diagrams that ask students to assess two competing scientific models by specifying whether certain pieces of evidence support or contradict each model (Chinn & Buckland, 2012). MEL diagrams relate to Question 6 in Table 1.

Second, during the school year, teachers attended eight after-school sessions to engage in lesson planning and mutual problem solving. Teachers were expected to design and implement three (week-long) lessons using argumentation, one per Quarters 2-4. A segment of each lesson was observed by a discourse coach, who were either teachers with more experience in argument pedagogy or employees of the district's professional learning office. After observing a portion of each learning sequence, the coaches used an observation form and a semi-structured feedback form that was utilized to set short-term goals for further teacher development.

Participants

Seventeen teachers attended the 10-day summer institute on pedagogy for scientific argumentation. Our research sample consisted of seven teachers who completed the entire PL, of which four taught in schools with large populations of ELs. Because one teacher did not emphasize CQs much and one taught at the same school as one of our target teachers (and therefore his data provided somewhat redundant information), we focus in this paper on analyzing the instructional and discourse practices of the two remaining teachers. Both participants taught eighth-grade science.

One teacher, Deborah, was an African American teacher who formerly taught high school but moved to middle school four years previously. Her school's student population was 27.9% EL, with a high rate of student transience (42.3%). Only 31.5% of the students were rated as proficient on the state's criterion-referenced test (CRT) for ELA. The other teacher, Elissa, was White, with a number of years of teaching experience. She was new to her school, having recently moved from another state, and had a reputation as a strong teacher. She and the other science teachers at her school were seeking National Board Certification. The student population at her school was 31.1% EL with 27.6% transiency. Only 32% of the students were classified as proficient on the state ELA test. Both teachers indicated that their schools placed a strong emphasis on student discourse, including argumentation. Both sought a better understanding of the science and engineering practice standard in the national science standards relating to arguing from evidence. Both also wanted knowledge of more tools to promote student discourse related to argumentation.

In terms of racial composition, the students at Deborah's school were 58.1% Hispanic, 23.4% African American, 5.9% Asian, 5.5% White, 5.3% two or more races, and 1.8% other. The students at Elissa's school were 83.7% Hispanic, 10.9% African American, 1% Asian, 2.3% White, 1.5% two or more races, and 0.7% other.

Research questions and data collection

The first goal of the research was to assess how the teachers used CQs and other tools to scaffold the discourse and learning of students. The second goal was to better understand the quantitative findings reported in Nussbaum et al. (2020), that among the students taught by the seven participants in our larger sample, students with lower prior-year ELA scores benefited the most from our program in terms of growth in student confidence to argue and on performance on an argument evaluation test (AET). Both of these measures were administered at the beginning and end of the school year. The AET measured students' ability to critique arguments, and whether they would spontaneously use the criteria reflected in the CQs. Given the large number of ELs in the school district (Spanish speakers plus a large range of other languages), and the low average ELA test scores in some of the participating schools, we hypothesized that student improvements were largely, though perhaps not exclusively, tied to language proficiency. While there were a number of features of the teachers' learning environment that could have contributed to growth, such as the extensive use of cooperative learning and language-oriented learning goals, we specifically sought to understand how the use of CQs and peer critique functioned in these teachers' classroom and how these might have contributed to student growth on our outcomes.

Data primarily included video transcripts of the three class sessions that each coach observed (including both whole-class and some small-group discourse), the coaches' written evaluation and feedback forms prepared after each observed lesson, student work samples from these lessons, and exit interviews conducted with each teacher jointly with their coach. We also examined lesson plans and transcripts of the PL. Using content analysis (Berg, 2001), we first examined and coded the data for categories related to the research questions. We then further identified themes within and across teachers and identified illustrative cases. Claims made by participants in the exit interviews were tested through triangulation with other sources of data.

Results

Use of graphic organizers and critical questions

Both teachers incorporated various graphic organizers into their lessons. Deborah consistently used the argumentation mapping tool. This involved students working in small groups to construct a CER and then using CQs to critique another group's CER, discussing the critiques in class. This was followed by individual students preparing their own individual CERs. Elissa used the mapping tool in a similar fashion during the last two quarters, and in Qtr. 4 also had students critique one of their old CER's. In addition, Deborah extensively used MEL diagram activities, which implicitly highlighted CQ6 regarding alternative explanations. Elissa tended to try out various graphic organizers, some of which contained CQs. Elissa also extensively used talk stem cards that reflected accountable talk moves (Michaels & O'Connor, 2012), often giving students one or two to work on in a lesson. During the exit interviews, both teachers thought that the organization provided by graphic organizers was very valuable for their students, especially ELs.

Regarding CQs, Deborah had students systematically answer all the CQs in Table 1, whereas Elissa only emphasized the first four, primarily because of time constraints. During the exit interviews, Deborah and Elissa indicated that they liked how the CQs helped to structure and focus students' thinking and discourse, and kept the discussions more on-topic.

Effects of critical questions

Elaborating student thinking and writing

Deborah and her coach reported that because many of the students were ELs, they needed help with completing their thoughts when writing. Many of the critiques prompted by the CQs involved the need to explain more, or to include a "because" or "why." Deborah indicated during the exit interview that many of her students had to be pushed to write something, and the CQs were useful, for example, in pushing students to make their evidence more specific (e.g., not just referring to "the lab" but to what was actually done and observed). Lesson transcripts showed that students' critiques often related to being clearer, writing more, giving details and specifics, explaining reasoning, and not just answering a CQ with a "yes or no." The CQ regarding whether an argument created a path that could be followed or whether there were missing steps was often used to criticize arguments for lacking details. The CQ regarding "good evidence" was also productively used. As noted above, evidence was criticized if it was not clear, specific, and relevant. We observed one group reporting that this critique was helpful and that they would "explain more next time." In facilitating oral discussion, we observed that Deborah would sometimes push students to elaborate their critiques, specifically by using CQs as probing questions, e.g., "What do you mean?" "How do you know that?" or "What type of evidence?" By Qtr.4, students were asking "why questions" of one another. Deborah's coach explained in the exit interview that Deborah's students, compared to students in general, became less likely to answer questions with "I don't know" or just a "yes or no" and that this was a big deal. In the beginning, some students didn't finish the mapping tool, but they kept at it and got better over time. They also improved in making claims, evidence, and reasoning to all relate to one another and make sense. In addition, they were having "little discussions about what constitutes evidence" (for example, does the use of Punnett Squares in genetics constitute evidence?). Table 2 shows the content of a completed mapping worksheet where one group completed a CER argument and another group used CQs to critique it on the topic of whether mutations are helpful, harmful, or both.

Table 2: Completed mapping worksheet on genetic mutations completed during Qtr. 4

<table>
<tr><td colspan="3">Left Column Work – Group Number: 3
Right Column Analysis – Group Number: 7

Argument Analysis Mapping Process: Critical Questions</td></tr>
<tr><td>Claim
(conclusion)</td><td>I claim that genetic mutations can almost always cause harmful change to an organism</td><td rowspan="3">1. Structure: Is there an argument here?
Can I underline to claim? (claim or conclusion)
Can I add a star* to the evidence (evidence)?
Can I [bracket] the reasoning (reasons)?
Yes there is an argument here.

Critical Questions:

2. Is there evidence?
How good is the evidence?
It's not very good at all. Says what we've done. Not really supporting the claim at all. And some of the evidence is in the reasoning. I suggest for evidence you shouldn't talk about what we've done in class but talk more about a mutation that was harmful, to support your claim.

3. Are any of the reasons untrue or incorrect? No

4. Does the argument use or connect with accepted scientific laws?
Yes, just not the evidence.

5. Do the parts of the argument make a path you can follow or are there missing steps?
Yes. Just not the evidence.

6. Are there other claims or conclusions that also fit the evidence?
Can you rule out other or competing claims or conclusions?
Well the evidence doesn't support any claim only their reasoning does. So you can't rule out any based on the evidence.

7. What is missing or weak in the argument?
It's missing evidence, it doesn't support the claim so it makes the argument weak.</td></tr>
<tr><td>Evidence
(observation, text, data, etc.)</td><td>• Our class made posters about how mutations affect your life.
• Our class watched a slide show on how different mutations occurred.
• The class researched about different mutations and diseases.</td></tr>
<tr><td>Reasoning
(describe the science concept of the evidence used to justify the conclusion)</td><td>1) For example, a mutation called SLOS causes mental retardation which leads to small heads, split upper lips, and extra fingers and toes.
2) Some mutations occur when having certain genes or genetics.
3) Some mutations temporarily damage your organs forever or it can kill you.</td></tr>
<tr><td colspan="3">Notes. Student writing is in italics. Grammatical and spelling mistakes have been corrected.</td></tr>
</table>

Elissa also reported that CQs helped students elaborate more in their writing. In the exit interview, she stated that "students were writing literally a couple sentences at the beginning of the year, now they are writing full page paragraphs, across the board, almost all of them….I think the CQs and the MELs contributed, what good evidence in science looks like." (Elissa's Qtr. 3 lesson discussed how good evidence needed to be concrete, relevant, thorough, and persuasive.) There was also evidence that CQs helped to stimulate more elaboration during oral discourse. Elissa noted that critical questions were easy for her to integrate into her lessons and the discourse, as her students already did a lot of peer review. She found that having students evaluate one of their old CERs was very effective. During the exit interview, Elissa indicated that students would state, "I don't follow this" or "that's kind of incorrect, because evidence right here says that…." We also observed a number of students asking "why questions" during Qtr. 4 (e.g., Why do you think that?). Like in Deborah's classroom, CQs were used to prompt elaboration. Elissa's coach indicated that from her three observations, she noticed that by the end of the year students were using the CQs and talk moves more and were having productive discussions. Both teachers indicated that CQs were especially valuable for "reluctant writers" who, according to the teachers, had to be pushed to complete their thoughts or make their evidence more specific.

Appropriation of technical terms

Deborah's coach indicated in the exit interview that her students "actually used some of the words in the questions to kind of help them state what they're thinking." Deborah also provided students with technical terms that could be used in their critiques. For example, one group wrote in their critique of another group's CER that they had "no clear support," incorporating the term *support* into their discourse. During Qtr. 4, another group incorporated the term *structure* into the oral discourse (and into their written critique), as follows.

Guillermo:	What is missing? Can we just say basically everything? Well, except for the claim.
Placida:	Structure.
Guillermo:	Oh, yeah, structure is an actual good word to use.
Placida:	They don't have a structure. There's missing parts.
Guillermo:	What is missing is they don't have a strong structure. What kind of structure?
	[Teacher makes an announcement]
Guillermo:	But be more specific. Like what kind of structure are you talking about?
Placida:	Specific.

The discussion relates to CQ7 from Table 1 regarding completeness. The technical term *structure* was contained in CQ1, but here the students appropriated the term and used it in the discussion of another CQ. The excerpt also reflects the classroom norm of being specific when providing reasons and evidence. Student appropriation of argument-related language was not mentioned by the teacher or coach in Elissa's classroom.

Growth in student confidence to critique

Deborah's coach observed that the students were often reluctant to disagree with one another or critique one another's arguments. Her coach wrote that at first Deborah's students were very "...reluctant to discuss or express their ideas in a class or group…." But with time and practice, Deborah's students became more comfortable and confident with argumentation, and "more open in their ideas, relied less on the thoughts of Deborah, and led small-group discussions to effectively understand new phenomena." Likewise, for Elissa, both she and her coach reported that over time, students used more CQs and engaged more in argument critique. Both teachers underscored that critique will help others strengthen their arguments and, according to her coach, Deborah fostered a warm classroom environment that supported peer critique.

Discussion

The themes that emerged from the qualitative analysis were that engaging in collaborative argumentation involving peer critique pushed the students to elaborate their thinking and discourse and appropriate in some cases argument-related language. This was accompanied by increases over time in these students' confidence to engage in critique. The results suggest that using critical questions can allow students to participate in argument discussions more fully and to think about the science content for longer periods of time. In combination with the quantitative evidence reported in Nussbaum et al., 2020, the evidence indicates that CQs are especially beneficial for students with low ELA scores. Some CQs also are fairly short, making it easier for these students, especially ELs, to appropriate the language and use the CQs to participate in discussions, for example by asking "why" or "how do you know?" questions (see Nussbaum, 2002).

Use of CQ may also have the added benefit of helping to differentiate instruction. Given the high student transience rates in these schools, we conjectured that peer critique allowed students who were new to a classroom to receive feedback and scaffolding to write more fully. Many of these students presumably generated relatively unelaborated arguments, which provided additional material for other students to critique. Students in a given classroom for close to an entire year benefited by becoming more proficient and confident in more advanced elements of argumentation critique. These conjectures do need additional empirical confirmation but point to how CQs might function to provide differential levels of support in classrooms with high transiency and high numbers of ELs.

Our qualitative findings help to explain our quantitative findings (reported in Nussbaum et al., 2020), based on survey and test data, that the confidence of students with low ELA scores for engaging in critical argumentation grew over the course of the year, and that they became increasingly more willing to challenge the premises of an argument on a written transfer test, for example counterarguing that "the Earth is not cooling" in response to arguments against human-induced climate change.

Intervention studies with ELs in U.S. science classrooms within the last two decades have noted the importance of engaging students in reform-oriented discourse practices (i.e., speaking and writing) for ELs' academic development (e.g. Lara-Alecio et al., 2012; Lee et al., 2005; Llosa et al., 2016). However, the majority of previous work has been situated in 3rd-5th grades, with little focus on argumentation. Studies on argumentative practices focused on second language learners such as Liu and Stapleton's (2020) tend to be situated in non-U.S. classroom contexts. This study adds to the much needed work examining reform-oriented practices for ELs and students with low ELA scores in secondary science in the U.S. contexts, in addition to focusing on effective argumentation practices and scaffolds related to argument construction and critique.

We recognize that all science students may benefit from the asking and answering of critical questions and the student discourse that CQs are intended to promote. They are, however, particularly beneficial for students with low ELA scores, including "reluctant writers" and ELs. This is notable because some teachers may believe that engaging in more than the most basic forms of argumentation is beyond the abilities of these students. We argue to the contrary.

Undergraduate Students Reasoning about Genetic Mechanisms

Michal Haskel-Ittah, Weizmann Institute of Science, Haskel@weizmann.ac.il
Ravit Golan Duncan, Rutgers University and Visiting Faculty Program Fellow at the Weizmann Institute of Science, Ravit.duncan@gse.rutgers.edu

Abstract: In genetics, a domain with a vast impact on citizens' lives, mechanistic reasoning is challenging. In order to promote the ability to reason mechanistically in genetics, we should first understand what knowledge students need in order to be able to provide mechanistic explanations in this domain. In this study we interviewed undergraduate students studying toward a biological sciences degree and asked them to explain several complex genetic phenomena. We analyzed those interviews via two complementing perspectives – a mechanistic perspective and a cognitive perspective for domain-specific reasoning. We identified the type of domain specific knowledge used by students for reasoning and their use of domain general principles for mechanistic reasoning. We found that domain specific knowledge is used to operationalize domain general principals such as identifying and unpacking entities and linking between different parts of the suggested mechanism. We also found that domain-specific knowledge is used for re-visiting one's own explanation.

Introduction and theoretical framing

Since the days of the scientific revolution, the search after the mechanisms underlying natural phenomena have become central in science (Shapin, 2018). The centrality of mechanisms in science has not escaped the attention of science educators, and the importance of mechanistic reasoning for the development of scientific expertise is well acknowledged. One of the goals in science education is to provide students with the ability to reason with and about the mechanisms underlying natural phenomena they may encounter in their everyday lives. This is because reasoning about such mechanisms leads to a better understanding of phenomena and provides one with the ability to explain and critically think on other explanations (Ahn & Kalish, 2000; Koslowski, 1996). Mechanisms consist of entities with specific properties that enable them to conduct certain activities (Craver & Darden, 2013; Machamer et al., 2000). These activities cause changes which eventually lead to the observed phenomena (Craver, 2001; Darden, 2008). Hence, to understand a mechanism and to reason about similar mechanisms, one should be able to identify and characterize the entities involved in the mechanism, and recognize the activities and functions executed by those entities (Russ et al., 2008). Those entities and interactions should be at least one organizational level lower than the phenomenon itself, and they should be able to explain how interactions between entities at this level lead to the final outcome – the phenomenon (Krist et al., 2018).

Studies in science education suggest that mechanistic reasoning is challenging across all ages and domains (Abrams & Southerland, 2001; Kampourakis & Zogza, 2008; van Mil et al., 2013) (Abrams et al., 2001; Kampourakis & Zogza, 2008; van Mil et al., 2013). For example, Students tend to focus on "why" phenomena occur instead of "how" they occur – a teleological view (Kampourakis & Zogza, 2008; Tamir & Zohar, 1991). It was also shown that novices tend to focus on components (structures) instead of interactions and processes, and that they experience difficulties in connecting elements (components and processes) into a complete mechanism. (Assaraf & Orion, 2005; Hmelo-Silver & Pfeffer, 2004; Ruppert et al., 2017).

In our work we focus on the domain of genetics and the complicated mechanisms involved in genetic phenomena. The ability to reason mechanistically in genetics is important due to the prevalence and impact of genetics on citizens' everyday lives. Genetically modified food, Gene therapy and genetic testing are examples for how issues from the field of genetics may appear in the everyday lives and require citizens to take a stand or make decisions. In order to make informed decisions in such issues some basic knowledge about how genetic information affects the final trait, i.e. genetics mechanisms and their involvement in trait formation, is needed (Boerwinkel et al., 2017).

However, many difficulties were characterized in reasoning about the domain of genetics and specifically in understanding the entities involved, their functions and how they interact and affect the observable trait (e.g. Duncan & Reiser, 2007; Haskel-Ittah & Yarden, 2018; Lewis et al., 2000; Marbach-Ad & Stavy, 2000; van Mil et al., 2013). In addition, even when students understand genetic mechanism at some level, their conception about these mechanisms is often deterministic. Namely, they do not understand the dynamic nature of these mechanisms and how they interact with the environment (Haskel-Ittah, Duncan, & Yarden, 2020; Heine et al., 2017; Stern & Kampourakis, 2017). conceiving of genes as the direct, unmediated cause of traits may lead to views of socially constructed human differences as immutable and stable. Hence, such deterministic conception is not only incorrect but may also contribute to the development of stereotypic and racist views (Donovan, 2014, 2016; Keller, 2005).

If our aim is to promote students' ability to reason mechanistically in genetics and understand its dynamic nature, we have to understand what knowledge resources students need in order to be able to provide mechanistic explanations about dynamic genetic phenomena. By "dynamic genetic phenomena" we refer to various phenomena in which the environment is sensed by genetically based mechanisms and consequently activates respond mechanisms which affect traits. These phenomena are named "phenotypic plasticity" because the observed trait (phenotype) is plastic and can be changed as a respond to the environment. For example, skin color is a genetic trait that is affected by genes coding for proteins which are involved in the production of a pigment named "melanin". This trait is plastic in the sense that UV radiation sensed by the skin cells can enhance the production of melanin and its spatial organization in the cells and thus it makes the skin appear as darker (Miyamura et al., 2011).

Prior research in science education has argued that both domain-general and domain-specific knowledge is needed for mechanistic reasoning (Duncan, 2007; Krist et al., 2018). Domain-general knowledge provides strategies and heuristics for reasoning about mechanisms (Krist et al., 2018; Russ et al., 2008). For example, Krist (2018) suggested three general principles (heuristics) for supporting mechanistic reasoning in science: a) considering a lower scalar level – considering processes that occurs at the scalar level below the level of the observed phenomenon, b) identifying and unpacking entities – characterizing the entities involved in terms of their properties and functions, and c) identifying interactions between these entities and how they bring about the target phenomenon.

Domain-general heuristics, such as those noted above, are not sufficient to provide plausible and domain-appropriate mechanistic explanations. In order to "operationalize" the general heuristics one needs domain-specific knowledge about the type and nature of components and processes in the mechanism (i.e., what are the particular entities and interactions at the lower scaler level). Duncan (2007) identified two domain-specific knowledge resources that were relevant for explaining molecular genetics phenomena: one is principle-like knowledge elements that are applicable to a wide variety of phenomena in the domain of molecular genetics (termed domain-specific heuristics) and the other are schemas about key domain-specific mechanisms (termed domain-specific schema). Duncan's (2007) research focused on relatively simple molecular genetics phenomena which do not involve modulation by the environment. It is unknown whether the same domain-specific knowledge forms are used (and are useful) when reasoning about more complex genetic phenomena such as genetic plasticity ones.

Our previous work suggested that the two types of knowledge, general and domain-specific, interact and bootstrap each other during reasoning (Haskel-Ittah, Duncan, Vázquez-Ben, et al., 2020). This is because domain-specific knowledge is needed in order to instantiate the domain-general principles, and the latter can cue domain-specific knowledge. In the case of the process of identifying entities at a lower scalar level, domain-specific schemas may constrain the plausible entities and typical activities that can play a role in the mechanism at that scalar level. In fact, a mechanistic explanation, as defined by Russ et al. (2008) should include entities and activities embodied in such schemas, otherwise the mechanism cannot unfold and bring about its outcome. For example, the general principle of going down one level when discussing the symptoms of a disorder at the cell level (e.g. sickle cell anemia) suggests referring to the molecular level. However, there are many entities in the molecular level (proteins, membranes, genes), domain-specific heuristics and schema can specify which ones matter and how.

While these two types of knowledge (general and domain specific) were described in prior work, we lack a clear characterization of the interplay between them. Analyzing the interactions between domain-general and domain-specific knowledge occurring while students reason about complex genetic phenomena can shed light on the knowledge that is needed for mechanistic reasoning in this domain. Thus, our research questions were:

1. What are the domain-general knowledge and domain-specific knowledge resources used by students when explaining complex genetic phenomena?

2. How do these knowledge resources interact in the course of reasoning?

Methodology

Study context and participants

In this study we interviewed 25 undergraduate students at different levels of their studies toward a biological sciences degree. Seven students were 1st year students, 11 students were 2nd year students and seven students were 3rd students. All the students were studying toward a degree in a life sciences– related field (nutrition, animal sciences, biochemistry). While these majors do differ, they share some similar basic course requirements. Therefore, all of our students completed a basic cell biology course, and all of our second- and third-year students completed a basic genetics course.

Instruments and data collection

We asked students to explain three phenomena (tasks) that involved complex genetic mechanisms. We first presented the phenomenon and then asked students "how do you think this happens". We encouraged students to explain the underlying mechanisms and to elaborate on the mechanisms they suggested by asking them to explain how each part of their suggested mechanism happens. The three tasks were:

1. Tanning – students were asked to explain how tanning occurs as a result of sunlight.
2. Stunting – students were asked to explain how growth is inhibited in malnourished children, and how it may affect the offspring of these children (given the information that it indeed affect the children)).
3. Smell imprinting in worms – students were asked to explain how the offspring of worms conditioned to attract to a particular smell, were also attracted to the smell stimulus also despite not receiving a reward or conditioning.

All these tasks involve a genetically based trait (skin color, height, behavior of attracting to a smell) which is changed due to signals from the environment (UV light, lack of nutrients and odor molecules). These signals are sensed by the organisms and activates a respond mechanism which interacts with components in the genetic mechanism itself. For example, in the case of smell imprinting, the smell conditioning activated a respond mechanism which led to epigenetic changes (changes to DNA, but not to its sequence) that imprinted this type of behavior.

Analysis

We analyzed the interviews via two complementing perspectives – the domain-general mechanistic perspective developed by Russ et al. (2008) and Krist et al. (2018) and the domain-specific mechanistic perspective using the model developed by Duncan (2007).

We characterized the knowledge resources used by students while reasoning and sorted them as instantiations of principles (domain-general mechanistic perspective) or instantiations of domain-specific heuristics and schemas (domain-specific mechanistic perspective). Instantiations of domain-general knowledge were coded as follows: a) Students' consideration of a lower scalar level by identification entities at this level – this code includes two domain general heuristics (i.e considering the lower scalar level and identifying entities). we could not separate between the two because students' attributions to a lower scalar level was via entities at this level (Cells, tissue etc.). b) Unpacking of entities and interactions – namely referring to the functions conducted by the entities their properties and interactions.

Instantiations of domain-specific knowledge were coded as follows: a) domain-specific schemas – we coded for schemas which were previously identified such as Activate, Inhibit, Sensing Signaling, Regulation of gene expression, Catalyze and Transport (Duncan, 2007). We also searched for emerging new schemas. Schemas are mini-mechanisms which involve interacting entities, hence we searched for statements which describe interactions between entities (e.g. "The hormone activate growth" or "this substance binds to a receptor so that the receptor sends a signal"). b) domain-specific heuristics - we coded for schemas which were previously identified such as proteins-as-central, Genes-code-for-proteins and effects-through-interaction (Duncan, 2007). We also searched for emerging new heuristics. Exploring for heuristics was done by searching for "rule like" statements which repeated in several interviews (e.g. "processes in the body are regulated" or "epigenetics modifications may affect the offspring").

We then analyzed the interactions between the two perspectives and the knowledge involved. We searched for heuristics that were used for identifying entities at a lower level. For example, the heuristic "proteins are central" which was identified by Duncan (2007) may be used for focusing on proteins in a sub cellular level. Thus, we searched for instances in which students explicitly stated that X should be involved and then they refer to X in their proposed mechanism.

Results

Domain-general knowledge resources

1.Considering a lower scalar level

All students considered entities at a lower scalar level in their explanations. Almost all answers referred to cells and the more complex answers, namely the ones which involved multiple entities and interactions, involved sub-cellular entities such as genes, receptors or enzymes. Although answers varied in terms of their complexity, this consideration of a lower scalar level appeared in all answer. This suggests that at the university level students understand that the mechanism responsible for a particular phenomenon lies at a lower, hidden, scalar level than the level of phenomenon itself.

2. Unpacking entities and interactions at the lower scalar level

While all students identified at least one entity at a lower scalar level, not all of them could unpack or fully characterize these entities, namely they did not explain what are the biological functions of these entities and how they impact the mechanism. Instead they mentioned that these entities are needed or are changed in the mechanism, without explaining how exactly they are involved. For example, in the context of tanning:

Mor,1st year: The UV radiation gets in, it damages the cells so it changes the tissue so it looks darker

Interviewer: How does this happen?

Mor,1st year: The UV leads to a chain of reactions, electron jumps, and the cell is damaged.

This type of explanation does not unpack the cells, namely it does not specify the cell properties, function or interactions between the cell, UV and the color of the tissue. Instead it only suggests an unspecified causal relationship between these entities.

On the contrary some answers specifically explained what is the function of the identified lower-level entities. An example of this type is:

Lavi 3rd year: I guess there's a mechanism that reacts to radiation and leads to melanin production

Interviewer: How does this happen?

Lavi 3rd year: There is an enzyme that can produce melanin and this enzyme is genetic, there is a gene coding for it…. there are molecules which are light sensitive and when they absorb light… maybe they are transcription factors which activates this gene [coding for the enzyme].

In this case, Lavi specifies how the interactions between the "UV sensing molecules" and the gene for the melanin producing enzyme leads to an over production of melanin.

It is interesting to note that 12 out of 21 (57%) explanations of 1st year students did not unpack entities, 8 out of 33 (24%) explanations in 2nd year, and only 3 out of 21 in 3rd year (14%) did not unpack them either. Also, all students unpacked entities in at least one explanation out of the three tasks. These two findings imply that students understand the need of unpacking entities but the knowledge resources they have in the domain may not afford such unpacking.

Domain-specific knowledge resources

Domain-specific schema

We identified, across students' explanations, all the seven schemas which were originally identified by Duncan (2007): Activate, Inhibit, Sensing Signaling, Regulation of gene expression, Catalyze and Transport. We did not identify any new schemas. This finding suggests that these seven schemas are fruitful for reasoning in the contexts of simple and complex genetic phenomena.

Domain-specific heuristic

We identified in students' explanations the use of the following heuristics which were previously described by Duncan (2007): Gene-code-for-proteins, proteins-as-central and structure-function. We also identified new heuristics (see table 1).

Table 1 – Heuristics used by undergraduate students in order to reason about phenotypic plasticity mechanisms.

Heuristic	Description	Example
Biological-processes-are-regulated	There are regulatory pathways which can respond to different situations	"the body knows if there are enough nutrients"

Genes-are-inherited	Inheritance is the transfer of DNA/genes from parents to their offspring	"then these changed genes were transferred to the offspring"
Genetic-modifications-in reproductive-cells-are-inherited	Only changes in genes of reproductive cells are inherited	"[it affected the offspring], so it probably changed something in the gametes"
Epigenetics-modifications-are inherited/not-inherited	epigenetics modifications persist in offspring cells/ epigenetics modifications are deleted in the embryo	"the epigenetics modifications were transferred to the offspring"/ "it should have been deleted in the embryo, though…"
Genetic-information-is-stable	genetic information does not easily change	"it is unlikely that the genetic code was changed because of this"

Unlike Duncan (2007) which focused on heuristics related to molecular genetics, in this study we explored also for heuristics at other levels. Thus, some of the domain-specific heuristics we identified are more broad. For example, the heuristic genes-are-inherited is not specifically related to molecular level mechanisms and may be also used to describe more general, macro-level, genetic phenomena. The heuristic biological-processes-are-regulated is not only related to genetics but to biology in general thus may be used for reasoning in other biological domains. These examples imply that heuristics may be at several levels of domain-specificity. The fact that we identified several new heuristics and no new schemas in our exploration may suggest that some heuristics are more context dependent than others as opposed to schemas which seem to be less context specific (i.e., apply to many distinct phenomena in the domain). In addition, heuristics seem to and range at different level of domain specificity (e.g. biology – genetics – molecular genetic). It should be noted that domain-specific schema may also have different levels of specificity. For example, schemas such as "activate" or "inhibit" seems to be more general in scope than "sensing" or "catalyzing" which involve more specific activities.

Interactions between knowledge resources in the course of reasoning

In order to answer the 2nd research question we analyzed the interactions between the types of knowledge-domain-general and domain-specific and between heuristics and schemas.

As noted earlier, we found that not all students managed to unpack the entities they identified, meaning they did not explain how the identified entities are involved in the mechanism. For example, students described the involvement of cells without explaining what exactly was changed in the cells or how this change resulted in the given phenomenon or they suggested that an enzyme was affected without mentioning the enzyme's function and how it was changed. We suggested that this is due to missing domain specific knowledge. Such explanations did not include any schemas (i.e. the cells or enzyme did not have any function). Hence, we would like to suggest that the missing knowledge needed to operationalize entities in domain-specific terms are relevant schemas. By relevant schema, we mean a schema that is perceived by the student as relevant. In some cases, students invoked a particular schema in one context (where they perceived it as relevant) but not in another context (because they did not see it as relevant even though it was). This means that key to developing a robust ability to explain genetic phenomena is conditional knowledge of when different schemas (and presumably heuristics) apply and when they do not.

We also found that students made use of heuristics in order to identify plausible entities. For example, the heuristic proteins-as-central, which determines that proteins are central entities in genetics phenomena, was used when students identified proteins as entities in the mechanism once the phenomenon was framed by the students as a genetic phenomenon. The domain-specific heuristic genes are inherited was used when students identified genes as entities in the mechanism once the phenomenon was framed as involving inheritance. An example for such use is in the context of smell imprinting. Mor, 1st year student, tried to explain how the offspring of the worm were attracted by a certain smell while never being exposed to it (only their mother was):

> "They [offspring] get a similar genetic code so the smell triggers it [a pathway lead to moving toward the smell] ….it all makes me think that a change happened to the genetic code".

Mor used the genes-are-inherited heuristics to posit the genetic code as a central entity in the mechanism she later described.

In other cases, domain-specific heuristics served as a link between two parts of the mechanism, namely parts which were not clearly connected by interacting entities. For example, the genes are inherited heuristic sometimes served as a link between what happened in the parent to what happened in the offspring without a need to explain the entire process of inheritance in which egg or sperm cells are produced and then fuse during fertilization (meiosis, fertilization). Genes-code-for-protein heuristic served to link between the genetic information and the product of a protein without a need to explain how genes are information units that are "read" by the cell as instructions for making proteins though cellular processes called transcription and translation. For example, May 2nd year, explained that growth inhibition involved a genetic mechanism but at first she explained it at the level of gene and then linked it to the protein via the genes-code-for proteins heuristic: "Maybe something blocks the gene which encodes the proteins that signals the body to grow, so the gene is not translated into protein". May does not explain how genes code for protein or how gene translation occurs but uses this heuristic as an input (gene) – output (protein) link. These heuristics specify input and outputs of processes and thus serve as a bridge between different parts of the mechanism.

Interestingly we also identified another type of domain general strategy that students often used which was not previously identified by Krist et al., (2018) or Duncan (2007) as essential for reasoning but consistently appeared in students' explanations. This is the process of re-visiting the explanation and criticizing it. We found that students used domain-specific heuristics in order to scrutinize and criticize their suggested mechanism. For example, after suggesting that the DNA sequence was probably changed, Michal (1st year) acknowledged that "From what I know a gene is not easily changed" Michal is criticizing the plausibility of her explanation by using the genetic information is stable heuristic. Other examples are from students trying to explain how growth inhibition due to malnutrition may be inherited. Both students (Ohad, 3rd year and Yuval, 2nd year) criticized their explanation which involved inheritance of epigenetic modifications by using the heuristic epigenetics-modifications-are-not-inherited: "From what I remember the epigenetic control is removed" (Ohad, 3rd year); "I think these Methylations are supposed to open but maybe I'm wrong" (Yuval, 2nd year). In these cases, students questioned their suggestion that epigenetics modifications persist in the offspring. This heuristic, which is true for some, but not all, cases was used in order to suggest that if this "rule" is applied here than the suggested mechanism cannot exist.

Discussion

In this study we searched for the role of different types of knowledge resources, domain-general and domain-specific, and their interactions. While in the literature general practices and domain-specific resources previously described for mechanistic reasoning (Duncan, 2007; Krist et al., 2018) were used as two distinct perspectives in observing mechanistic reasoning, we found a deep almost inseparable connection between them. More specifically, our result imply that undergrad students appreciate the need to identify and unpack entities at a lower scalar level. However, their explanations sometime do not include this identification and unpacking because they do not have domain-specific schemas which can act as placeholders for the specific functions and interactions between these entities. Hence their explanations may seem as a list of causes without specifying the interactions between these causes, namely the mechanism.

A recent study of Chinese elementary school students suggested that children often focus on patterns or causal relationships instead of the mechanism (Tang et al., 2020). The study offered that this is the result of the Chinese national standards and curriculum which are more focused on the pattern seeking than on mechanistic reasoning. Our results imply that understanding the need of a mechanism is also not enough, if there are no knowledge resources in the domain which allow the unpacking of entities into a mechanistic explanation. Hence not only domain general strategies should be explicitly taught (as suggested by Krist et al., 2018) but also domain-specific schemas should be emphasized and their building should be scafolded as part or teaching students how to reason mechanistically in a certain domain.

Our study also dealt with non-mechanistic, but important, parts of mechanistic explanations – heuristics. By definition, the heuristics themselves are not mechanistic since they explain what happens and do not involve functions and interactions between entities and activities (Braaten & Windschitl, 2011; Craver & Darden, 2013). However, our results suggest that these non-mechanistic rules have several roles in the process of mechanistic explanations. First, they act in the process constructing the mechanism because they are used for evaluating the plausibility of the involvement of specific entities in the mechanism or the mechanism as a whole. In addition, it seems that these heuristics also act as links between parts of the mechanism thus are important for the ability to connect parts in the mechanism into a coherent explanation.

In summary, we found that domain general knowledge and domain-specific knowledge interplay while students' reason about genetic mechanism. Our study implies that domain-specific heuristics and schemas exist in several levels of domain-specificity and that heuristics are used for several purposes such as to instantiating the identification of entities and for bridging gaps in the mechanism and schemas are used for unpacking entities. We also found that heuristics may be used for the purpose of evaluating the plausibility of the suggested mechanism. This study also suggests that a dual perspective of both domain-general and domain-specific knowledge is fruitful for studying mechanistic reasoning and provide a wider picture on the reasoning process than each of the perspectives separately.

Instructional Implications

Our study reveals the importance of domain-specific and domain-general knowledge for the ability to reason mechanistically. This means that both types of knowledge should be targeted explicitly not only in undergraduate education but all along science teaching. Since heuristics are non-mechanistic but important parts of mechanistic reasoning, we offer that their distinction from mechanistic schemas will be also explicitly taught.

In our study we found domain-specific heuristic which lay at different specificity levels than others and we offer that some schemas are also more general than others. This point should be empirically tested, and if indeed such hierarchy exist it may suggest that more general biological heuristics and schema should be constructed at younger ages and become more specific at higher grades. In such manner, students may be able to construct mechanistic explanations in biology already at these younger ages and develop this ability along the school years.

Observing or Generating Solution Attempts in Problem Solving Prior to Instruction: Are the Preparatory Processes Comparable?

Abstract: Problem solving prior to instruction (PS-I) approaches have been found to facilitate students' conceptual learning. It has been argued that the problem-solving processes prepare students for subsequent instruction. During problem solving, students are asked to generate multiple solutions to a novel problem. Yet, it is still unclear whether students actually need to generate solutions themselves to be prepared for learning from instruction or whether they could also receive solution examples and study those. Recent findings are mixed, requiring further analyses that investigate the preparatory processes during both types of activities. In this paper, we investigate students' cognitive processes during generation and observation of solution attempts in order to better understand and design for the preparatory mechanisms in PS-I. We hypothesized that both activities would involve similar cognitive processes for the preparation of subsequent learning. Our results confirm this comparability, suggesting that similar preparatory processes are at work.

Introduction

Recent research has demonstrated the success of instructional approaches that emphasize the role of problem solving prior to instruction (PS-I) for learning (for a review, see Loibl et al., 2017). Students, who participated in problem solving followed by direct instruction, were shown to perform higher in a conceptual knowledge test than students who received instruction first and practice problems after (I-PS) (e.g., Kapur, 2014b). Despite the success of PS-I, we still lack a full understanding of the cognitive mechanisms that prepare students for subsequent learning. Loibl et al. (2017) proposed three preparatory mechanisms: prior knowledge activation, awareness of knowledge gaps, and deep feature recognition. The present paper focuses on the preparatory mechanism *prior knowledge activation*. In our PS-I setting, which is also referred to as Productive Failure (PF) task, students in the problem-solving phase are instructed to generate multiple solution approaches to a novel and challenging mathematical problem (Kapur & Bielaczyc, 2012). The generation of different solution attempts is presumed to encourage students to activate and differentiate relevant prior knowledge, which facilitates processing the subsequent instruction (Kapur & Bielaczyc, 2012). While prior knowledge activation is assumed to be a core mechanism of PS-I (Kapur & Bielaczyc, 2012; Loibl et al., 2017), it is unclear whether the preparatory effect of prior knowledge activation is only afforded by generating solution oneself. In order to further examine this preparatory mechanism, studies have investigated whether observing examples of students' failed solution attempts has similar preparatory effects as generating solutions oneself (e.g., Hartmann et al., 2020, 2021; Kapur, 2014a). Kapur (2014a, 2014b) asked students in a so-called Vicarious Failure (VF) condition to evaluate examples of other students' solution attempts. Results showed that the VF students outperformed I-PS students in a knowledge test, indicating that VF students were prepared for subsequent learning. However, VF students were outperformed by PF students, suggesting a higher preparation effect in the PF condition. In contrast, Hartmann et al. (2021) found that students who generated solutions themselves (PF) did not perform better than those who observed examples of PF students' complete problem-solving process (VF). The mixed findings suggest that further research is needed to examine the comparability of the preparatory mechanisms at work in PF and VF. More specifically, empirical evidence is needed on the preparatory processes of knowledge activation. This paper aims to shed further light onto students' cognitive processes during both types of preparatory activities (i.e., problem solving in PF and observation of examples in VF) by comparing the think-aloud recordings (i.e., their verbalized thoughts) of matched PF and VF model-observer-pairs. In the following, we give an overview of relevant prior research and describe potential PF and VF cognitive processes.

Problem solving and observing examples as preparatory activities

When students in PS-I generate solutions to a novel problem which they are not yet able to solve, they are assumed to activate relevant prior knowledge and become aware of the limits of this knowledge. For instance, in a typical PF task about the concept of standard deviation, students need to find the most consistent soccer player based on the goal scores of three players within ten years. During subsequent instruction, students then receive an explanation about common mistakes in student solutions, which aims to relate to their knowledge gaps and facilitate the integration of new knowledge about the deep features of the canonical solution (e.g., standard deviation) (Loibl et al., 2017; Loibl & Rummel, 2014b).

Kapur and Bielaczyc (2012) highlighted the importance of generating own solution attempts during the problem-solving phase to afford prior knowledge activation. However, the specific processes underlying prior knowledge activation in PS-I still remain unclear and might not be exclusively related to the generation of own solution attempts. For instance, research on worked examples suggest that the observation of examples could serve as a similar or even better preparation for subsequent learning than problem solving (cf. Likourezos & Kalyuga, 2017; Newman & DeCaro, 2019). In an attempt to examine boundary conditions of PS-I, several studies investigated whether the observation of examples in form of students' solution attempts could also prepare for learning from instruction. In two experimental studies, Kapur (2014a, 2014b) designed VF conditions, in which he asked students to evaluate the validity of examples of erroneous and incomplete student solutions. Results revealed that evaluating examples prepared them for learning from subsequent instruction and lead to higher learning gains than those shown by students who received instruction first and practice problems after (I-PS). Yet, they were outperformed by students who generated solutions in a PF condition. In contrast, Hartmann et al. (2021) found that students of a VF condition who observed the problem-solving process of PF students, achieved equal learning gains as students of a PF condition and even outperformed them when they showed higher prior knowledge scores.

The recent findings by Hartmann et al. (2021) suggest that students in PS-I do not necessarily need to generate solutions themselves, but might achieve equal preparation for learning, by observing and making sense of another student's problem-solving process. Comparability regarding the preparation for learning would suggest that both, generating and observing solutions afford similar preparatory processes. However, overall, the comparison of learning gains in PF and VF has led to mixed findings. In order to find explanations for these findings and identify boundary conditions for the effectivity of PF and VF, it is necessary to achieve a better understanding of the cognitive processes afforded in both conditions. With this understanding, we can define relevant aspects for instructional designs that enable preparation for subsequent learning in PS-I. So far, the cognitive processes in VF have not been investigated and only few studies have attempted to describe the problem-solving processes within PS-I settings such as PF. Roll et al. (2012), Brand et al. (2018), and Brand et al. (2019) offered categorizations that divide problem solving in PS-I into different phases based on models of mathematical problem-solving or the inquiry cycle (cf. de Jong, 2006; Schoenfeld, 1985). We build upon these approaches and describe the cognitive processes of PF *and* VF students with the help of four categories: task orientation, engagement with solution attempts, elaboration of solution attempts, and evaluation of solution attempts (cf. Table 1). While the first three categories primarily feature prior knowledge activation processes, the fourth category deals with the metacognitive processes of evaluation and monitoring. All described processes can appear more than once and not necessarily consecutively during the preparatory activities (i.e., generation or observation of solution attempts) of both PF and VF conditions.

The first category is *task orientation*. In order to be able to engage in the preparatory activities, students have to understand the task's components and goal (cf. Roll et al., 2012; Schoenfeld, 1985). The students of both conditions receive the same problem about the formula of standard deviation (e.g., Kapur, 2012; Loibl & Rummel, 2014b). While the students of the PF condition are instructed to generate different solution attempts that display the consistency of three soccer players, the students of the VF group receive the problem as a basis for observation, but are not asked to generate solution attempts (cf. Hartmann et al., 2020, 2021). As both groups of students have not yet learned about standard deviation, it is plausible that both PF and VF students similarly need to form an understanding of what consistency means in the context of the given problem. For this task orientation, students might activate and reflect on their formal and informal prior knowledge about consistency in order to generate ideas or criteria that link their knowledge to the goal of the task. This can include both cognitive and metacognitive processes, however, we focus on the cognitive process of activating relevant prior knowledge for understanding the task.

The category e*ngagement with solution attempts* represents the main part of the preparatory activities in both conditions, the students deal with various solution attempts to the given problem. Roll et al. (2012) describe these processes as plan, design, and implementation stages. Both, generating solutions oneself (PF) and observing solutions (VF) require students to activate relevant prior knowledge. Even though both conditions implement different triggers for prior knowledge activation (i.e., generation versus observation of solution attempts), the VF observer has the opportunity to engage in the similar prior knowledge activation processes as the PF model through a step by step observation of the PF student's problem-solving process. Therefore, when the PF model comes up with a solution idea and starts to execute it (e.g., central tendencies such as mean, range or graphical solutions), the VF student observes the idea, which triggers the activation of relevant prior knowledge associated with the solution idea. Similar to the PF condition, students of the VF condition might think about own solution ideas. Additionally, they have the opportunity to compare their ideas with those of the PF model. Kapur (2012) showed that students generate a limited range of solutions that spans four categories. Therefore, we can expect students of both conditions to largely come up with the same types of ideas, and thus, to activate prior knowledge to a similar extent. Consequently, the observation and generation of solutions could trigger similar engagement with solution attempts in both conditions.

Elaboration of solution attempts defines another stage in the process: the analysis and interpretation of the solution attempts with regard to what they imply about the problem's solution (cf. Hartmann et al., 2021). In order to fully comprehend the implication, students need to interpret the results of their calculations in the context of the given problem (i.e., what do values such as the mean or range tell me about the consistency of the soccer players?). The students of both conditions are likely to engage in this process of sense-making in the same way in order to form an understanding of the present solution attempts. Through the analysis of solution attempts, students might be able to build an elaborated understanding of the generated solutions, that is, advancing and differentiating the knowledge that they activated when dealing with the different solution attempts (Kapur & Bielaczyc, 2012).

The last category is *evaluation of solution attempts.* In problem-solving, students rely on metacognitive skills such as monitoring and evaluation of the problem-solving process in order to ensure its success (Schoenfeld, 1985). Said metacognitive skills majorly come into play during the evaluation phase in PS-I, in which students evaluate the outcome of their solution attempts (cf. Roll et al., 2012). While students of the VF condition do not engage in the monitoring of their own problem-solving processes, they evaluate and monitor the problem-solving process of the PF model when trying to make sense of the PF model's solution attempts. As the students of both conditions deal with a novel problem, evaluation and monitoring processes could likewise encourage them to question the validity of solution attempts and become aware of their knowledge gaps (cf. Loibl et al., 2017). Additionally, monitoring processes of the PF model's problem-solving process could enable the VF student to identify errors or knowledge gaps in the PF model.

Based on the outlined cognitive processes in VF and PF, we hypothesize that a process analysis of the verbal reports of matched PF and VF model-observer-pairs (i.e., one VF student who observes the problem-solving process of one PF student) will show similar quantities of the outlined types of cognitive processes throughout both preparatory activities. That is, the model-observer-pairs will not significantly differ in the number of utterances related to the processes in each of the four categories discussed above.

Methods

Participants and design

The experimental study that provided the process data used in this paper was conducted in a German secondary school during regular mathematics classes (cf. Hartmann, 2020). The original sample of the study consisted of 110 students, who were randomly assigned to two conditions (i.e., PF and VF). Each student of the VF condition was randomly matched to students of the PF condition to form model-observer-pairs (PF: n = 55, VF: n = 55). During the preparatory activity, the students of the VF condition watched a live transmission (live screen recordings) of their matched PF students' handwritten notes during problem solving.

For the process analysis, we selected a subsample of 15 matched PF and VF model-observer-pairs (N = 30, PF: n = 15, VF: n = 15). In order to control for prior mathematical abilities (i.e., students' average of their last two grades in mathematics), which significantly predicted students' knowledge scores in the main sample, $r(108) = .71$, $p < .001$, the pairs were selected based on the similarity of their mathematical abilities. That is, only students with the same or minor differences (i.e., 0.5) in average grade were included in the subsample. A Bayesian paired t-test confirmed the comparability of the subsample and the main sample as the selected pairs showed equal conceptual learning scores, that is, the assumption that PF and VF pairs had similar learning scores (BF_{01}; H_0) is 2.11 times higher than the assumption of a difference in conceptual knowledge (BF_{10}; H_1).

Process data

For the process analysis, we used think-aloud audio recordings as an indicator of students' cognitive processes during problem solving in both conditions (cf. Ericsson & Simon, 1980). Based on the PF coding scheme by Brand et al. (2018), we developed a coding scheme that describes students' cognitive processes in PF and VF based on their utterances during problem solving. It includes four categories of processes: task orientation, engagement with solution attempts, elaboration of solution attempts, and evaluation of solution attempts. Each of the categories includes sub-codes that describe specific processes within each category, with 44 codes in total (see Table 1 for examples). *Task orientation* features codes that specify the components or goal of the given task. The category *engagement with solution attempts* includes codes about the generation or observation of solution ideas. Additionally, it describes three variables that only apply to the VF condition: two codes refer to VF students comparing their own ideas to the one's of their PF model. A third one functions as a manipulation check variable that includes statements, which indicate that the handwritten solution attempts were not comprehensible to the VF student. *Elaboration of solution attempts* describes students' analysis and interpretation processes such as deduction from the results of a solution (i.e., in terms of which player might be the most consistent). The category *evaluation of solution attempts* contains the metacognitive processes of evaluation and monitoring of one's own knowledge as well as an additional VF code, which outlines the identification of errors in the PF model's solution.

Table 1: Example codes and statements for each coded category

	Category	**Example code for the category**	**Example statement**
1	Task orientation	Definition of the task	*All given data needs to be included in the calculations.*
2	Engagement with solution attempts	Identification of solution ideas	*I/The model calculate(s) the mean.*
		Comparison of VF and PF ideas	*I had the same idea. // I would not have done that.*
		Incomprehensibility of PF ideas	*I cannot make out anything from what is written here.*
3	Elaboration of solution attempts	Substantiated deduction from results	*Mario is the most consistent player as he scores almost the same number of goals each year!*
4	Evaluation of solution attempts	Positive evaluation of solutions	*The first solution was really good!*
		Identification of own knowledge gaps	*I do not know whether this solution will work or not.*
		Identification of errors in PF model	*The solution does not make any sense.*

We coded the audio data with the software MaxQDA 2020. Prior to coding, the data was segmented by an expert who preselected on-task utterances for coding. Due to the high number of codes, the coding process was divided into two steps. First, all on-task segments of a student were assigned to one of the four categories, then, for each category separately, the utterances of the segments were tagged with sub-codes. 20% of the data was coded by two independent raters, showing an excellent agreement on both coding levels (categories: *ICC* (*3, 1*) = .90, 95% *CI* [.70, .98]; sub-codes: *ICC(3, 1)* = .92, 95% CI [.80, .99]). For the analysis, we counted the frequencies of each sub-code and calculated the sum for each category. The category sums only included variables, which occurred in PF and VF, while the VF variables (i.e., the comparison of VF and PF ideas and identification of errors) were summed up as a separate variable.

Procedure and materials

In the following, we summarize the relevant methods of an experimental study by Hartmann (2020) that provided the data for the present inquiry. The procedure and materials followed the same methodological protocol as previous studies in PS-I (see Kapur, 2012 for design of the PF problem; Loibl & Rummel, 2014b for design of the direct instruction and knowledge test). The experiment took place during two regular mathematics classes (90 minutes each). Before the first activity, the students were asked to complete a prior knowledge test and report their prior abilities (20 minutes). After that, students were randomly assigned to two conditions and engaged in the preparatory activities (45 minutes): the students in the PF condition were instructed to generate as many solutions to the given problem as possible, while the students in the VF condition received live transmissions of their PF model's handwritten solution attempts on a computer screen. The students were in the same classroom, but not aware of the identity of their matched partners as they were seated apart and with their backs to each other. During the time of the preparatory activity both groups of students were instructed to verbalize their thoughts. After that, students filled in a questionnaire to assess their awareness of knowledge gaps (5 minutes). In the following mathematics class, both groups jointly received a direct instruction (30 minutes) on the components of the canonical solution. Both, the preparatory activity and the instruction were conducted by the same trained member of the research team. Finally, the students filled in a knowledge test (30 minutes).

The problem used in the preparatory activity targets the formula of standard deviation. It asks students to find the most consistent soccer player among three based on a data table that displays the players' goal scores across ten years. The final instruction was based on typical erroneous student solutions and explained the components of the canonical solution. Prior to the preparatory activity, we assessed the students' last two grades in mathematics, their prior knowledge, and their mathematical self-concept. The students' prior knowledge was measured with a knowledge test consisting of five tasks on descriptive statistics (i.e., mean and range) (Cronbach's alpha = .32; reliability measures for the whole sample). The low Cronbach's alpha value likely resulted from the fact that various mathematical concepts were tested that did not necessarily interrelate. The measures for mathematical self-concept were adopted from Rost and Sparfeldt (2002) and included the students' belief about their mathematical skills (e.g., '*It is easy for me to solve problems in mathematics.*') with eight items on a 6-point

Likert scale (Cronbach's alpha = .93). The final knowledge test after instruction included eight tasks on students' conceptual (Cronbach's alpha = .67) and four tasks on their procedural knowledge (Cronbach's alpha = .87). 20% of the students' knowledge tests were coded by a second rater, showing high reliability for all items (*ICC (2,1)* = .97, 95% *CI* [.93, .99]).

Results

Prior to the process analyses, we examined the VF manipulation check variable. The variable assessed whether students of the VF condition struggled to comprehend the PF model's problem-solving process. The analysis of the variable revealed no concerns for a failure of manipulation as only minor difficulties such as reading problems occurred, all of which were resolved later on in the activity. In total, we coded 1559 utterances. 1459 utterances referred to processes that could occur in both conditions and an additional 100 to processes unique to VF. Out of the 1459 utterances, students in VF produced 782 (M = 58.80; SD = 23.09) and students in PF 677 utterances (M = 45.13; SD = 16.98). Table 2 shows the ranges, means, standard deviations, and frequencies of each category of the coded processes for both conditions (excluding VF-only processes). In both conditions, utterances coded as *task orientation* occurred the least, *engagement with solution attempts* the most. The frequency of the processes varies a lot between individual students as shown by the high standard deviations. Descriptively, the analyses reveal that the quantity of cognitive processes per category was largely similar for both conditions, except for category 4, in which the average frequencies of PF and VF processes differed descriptively by 9.33.

Table 2: Descriptive statistics of the four categories of PF and VF processes (PF: n = 15, VF: n = 15, N= 30)

	Task orientation			**Engagement with solution attempts**			**Elaboration of solution attempts**			**Evaluation of solution attempts**		
	PF	**VF**	**Total**	**PF**	**VF**	**Total**	**PF**	**VF**	**Total**	**PF**	**VF**	**Total**
M	2.33	2.27	2.30	26.00	29.67	25.77	6.2	4.40	5.30	10.60	19.93	15.27
SD	1.80	2.76	2.29	10.17	12.91	10.46	3.65	2.75	3.30	7.03	9.85	9.66
range	0-6	0-8	0-8	12-52	10-54	9-52	1-12	0-9	0-12	4-26	1-36	1-36
freq (%)	35 (5.17%)	34 (4.35%)	69 (4.73%)	390 (57.61%)	383 (48.98%)	773 (52.98%)	93 (13.74%)	66 (8.44%)	159 (10.90%)	159 (23.49%)	299 (38.24%)	458 (31.39%)

Additional to the 782 VF processes above, Table 3 presents the descriptive data for the processes that were unique to VF, excluding the manipulation check variable as it does not provide further information about VF. The remaining three processes amounted to 62 utterances (7.03% of all VF processes). The first two VF variables can be assigned to category 2, *engagement with solution ideas*, and describe the comparison of a VF student's own solution ideas with those of their PF model (agreement vs. disagreement). The last variable describes the identification of errors in the solution attempts of the PF model and is part of the category 4: *evaluation of solution attempts*. Out of the three variables, the identification of errors appeared most frequently.

Table 3: Descriptive statistics for variables that could only occur in VF (n = 15)

	Comparison of PF and VF ideas (agreement)	**Comparison of PF and VF ideas (disagreement)**	**Identification of errors in PF solutions**	**VF-only processes (sum of all variables)**
M (SD)	0.93 (1.83)	0.67 (0.90)	2.53 (2.92)	4.13 (3.50)
range	0-6	0-3	0-9	0-12

We hypothesized that the quantity of utterances (i.e., students' cognitive processes) in each of the four categories would not differ between PF and VF pairs. To test our assumptions, we calculated four Bayesian paired samples t-tests, one for each of the categories (calculated in JASP 0.14.00, for information on Bayesian statistics see Wagenmakers, Love et al., 2018; Wagenmakers, Marsman et al., 2018). The paired sample tests assessed the mean differences for each of the 15 matched model-observer-pairs. Figure 1 shows the plotted results for categories 1 to 4. Panel A shows the results for the category *task orientation*. The Bayes factor indicates that based on the given data the assumption that the matched model-observer-pairs in PF and VF do not differ in the number of task orientation processes (BF_{01}; H_0) is 3.80 times more likely than the assumption that PF and VF pairs differ in this category (BF_{10}; H_1), presenting a moderate evidence for our hypothesis (cf. Wagenmakers, Love et al., 2018 for interpretations of Bayes factor). Panel B shows the plot for the category *engagement with solution attempts*. The Bayes factor gives an almost moderate evidence for the assumption that PF and VF pairs do not differ in the processes that deal with the generation and observation of solution attempts (BF_{01}; H_0), with a likelihood that is 2.65 times higher than the assumption of a difference between pairs (BF_{10}; H_1). Panel C shows with an anecdotal evidence for category 3 (*elaboration of solution attempts*) that the assumption that PF and VF pairs differ in analysis and interpretation processes is 1.56 more likely (BF_{10}; H_1) than the assumption that PF and VF pairs are similar (BF_{01}; H_0). Panel D represents the category *evaluation of solution attempts*. The Bayes factor indicates a moderate evidence for the assumption that PF and VF pairs differ in the frequency of evaluation and monitoring processes (BF_{10}; H_1), with a likelihood of 4.31 times higher than the assumption that they do not differ (BF_{01}; H_0).

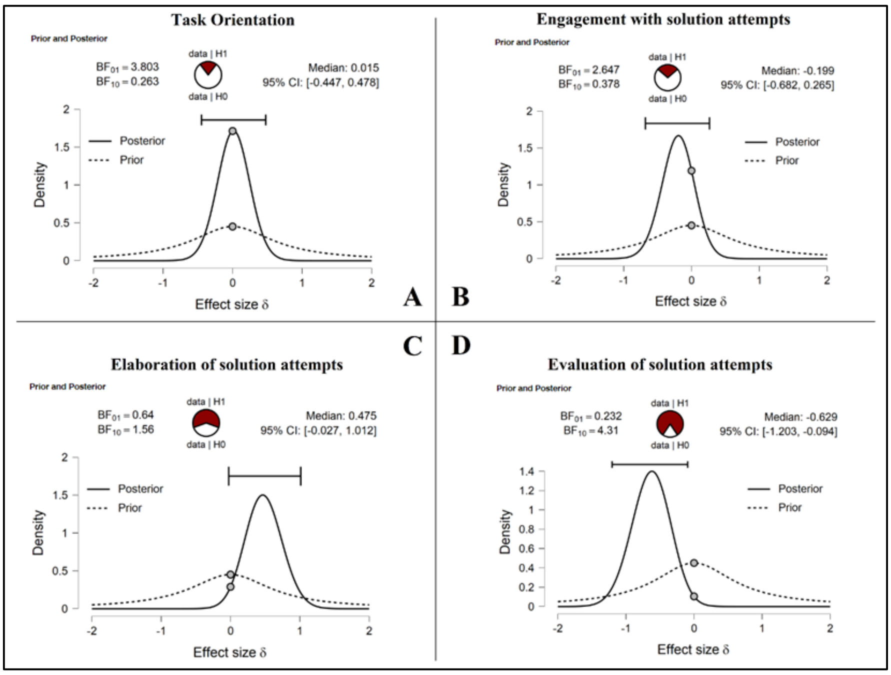

Figure 1: Plots of the Bayesian paired samples t-tests for all four categories

Discussion and conclusion

This paper explored the preparatory activities of two instructional settings in the field of PS-I: PF and VF. Research so far has presented mixed findings regarding the comparability of both activities, requiring further insights into the cognitive processes occurring in both PF and VF. We argued that students in both conditions show similar cognitive processes (i.e., prior knowledge activation and metacognitive evaluation and monitoring processes) as students in VF are encouraged to understand and follow the problem-solving processes of a PF model. We hypothesized that PF and VF model-observer-pairs would not differ in the quantity of verbalized cognitive processes in four categories: *task orientation, engagement with, elaboration of, and evaluation of solution attempts*. Our analyses confirmed our hypotheses for category 1 and 2 with moderate and near moderate evidence for the similarity of matched pairs in *task orientation* and *engagement with solution* processes. While our data indicated a difference between pairs for the category *elaboration of solution attempts*, this evidence was only anecdotal, meaning that it was almost as likely that students differ in this category as it was likely that they are similar. Descriptive statistics revealed that the conditions differed only by an average of two cognitive processes that were coded for this category. Taken together, these results indicate that indeed students in the PF and VF conditions display largely similar prior knowledge activation processes. Furthermore, the students' prior knowledge processes in the category *engagement with solution attempts* (i.e., the generation or identification of solution ideas) appear to constitute the largest part of students' processes, suggesting that the significance of prior knowledge activation as a preparatory mechanism might be higher than previously assumed.

Contrary to our hypothesis, PF and VF pairs differed in category 4, *evaluation of solution attempts*, which focuses on the metacognitive processes of evaluation and monitoring. Descriptively, students of the VF condition showed higher average amounts of evaluation and monitoring processes than students of the PF condition. Thus, VF students appear to not suffer losses in the preparation for subsequent learning but rather show additional metacognitive activities (i.e., evaluation and monitoring) compared to their PF models. Looking at the processes that only VF students can engage in such as the comparison of own ideas with those of the PF model and the identification of errors by the model, emphasizes the additional potential of the VF condition. The descriptive analyses revealed that the metacognitive process of error identification occurred most frequently out of the processes that were unique to the VF condition. Overall, the VF condition appears to show an additional engagement in evaluation and monitoring processes. This finding can be explained in the light of research on worked examples. Studies showed that problem solving imposes high cognitive demands on the learner as problem solving requires high working-memory resources when searching the problem space for potential solution steps (Sweller et al., 1982). Worked examples reduce the cognitive demands on the learner as they already present the correct solution steps (cf. Sweller & Cooper, 1985). Similarly, VF students do not have to engage in problem solving themselves, relieving them from the cognitive demands that come with the search of problem-solving operators (i.e., mathematical tools or ideas to solve the problem) or next steps in the generation of a solution. Thus, observing examples in VF might free students' cognitive capacities compared to the PF students, enabling them to engage in more evaluation and monitoring processes. Kapur (2014a) indeed found that PF students reported higher mental effort than students in VF. Further studies are needed to investigate the cognitive demands of examples of failure in the form of live-modeling examples on VF students as compared to a PF setting.

Overall, our inquiry confirmed a comparability of PF and VF with regards to their cognitive processes in our subsample. The model-observer-pairs largely did not differ in their prior knowledge activation processes. While PF and VF did differ in the frequency of evaluation and monitoring processes, this was due to a higher frequency in VF, which still enable comparability and indicate additional potentials of the VF condition. This allows concluding that PF and VF are comparable in their preparatory processes. The students of both conditions experienced not only similar preparatory processes, but also equal learning scores after instruction (see methods section for Bayes factor). These findings offer valuable information for future research and educational practice. Firstly, they take us one step further in identifying relevant aspects for the development of instructional designs that facilitate learning in PS-I. Future instructional designs can implement both PF and VF activities in order to afford the preparatory of prior knowledge activation. This offers new methodological possibilities to investigate PS-I preparatory mechanisms. For instance, so far, measuring and controlling the preparatory mechanism of prior knowledge activation has proven to be challenging. While different measures for prior knowledge activation were explored such as the quantity, quality, and diversity of solutions (i.e., the number of conceptually different solution attempts), only correlational relationships with learning were assessed and yielded mixed findings (e.g. Kapur, 2012; Loibl & Rummel, 2014a). However, the comparability of PF and VF enables future studies to employ VF conditions to experimentally variate prior knowledge activation by showing students of a VF condition different types of solution ideas. This could provide valuable insights for understanding the preparatory effects in PS-I. Secondly, in educational practice, learning from students' examples presents an efficient and resource-saving instructional approach compared to PF. Moreover, the generation of erroneous solutions usually deviates from students' socio-mathematical expectations (i.e., the instructional methods they expect in mathematics classes) and students might be more used to studying examples. Therefore, the latter could function as a more accessible preparatory activity (cf. Kapur & Bielaczyc, 2012).

We would like to highlight some limitations of our inquiry. The high standard deviations in the descriptive data indicate that the quantity of students' cognitive processes varied a lot between participants. As the processes were based on think-aloud data, this could indicate that the number of coded utterances could have been confounded by individual factors such as students' mathematical self-concept, how comfortable students were in verbalizing their thoughts, and general willingness to communicate. However, students' self-concept was not associated with the total number of utterances, $r(28) = .04$, $p = .84$.

In conclusion, the present research dealt with the preparatory activities in two PS-I settings: PF and VF. Previous studies examined whether students need to generate own solutions in order to be prepared for learning from instruction (e.g., Hartmann et al., 2020, 2021, Kapur, 2014a). Hartmann et al. (2021) found that VF students were equally prepared for subsequent learning than a PF condition. As a follow-up, this paper investigated the cognitive processes of PF and VF model-observer-pairs, hypothesizing that PF and VF students are equally prepared for subsequent learning. Our analyses revealed that the PF and VF pairs indeed showed similarities in their preparatory processes, specifically in their prior knowledge activation processes. Moreover, VF appeared to show additional potential for metacognitive evaluation and monitoring processes.

Effective Middle-School Collaborative Geometry Learning: A Dialogic Discursive Lens

Abstract: To understand how students' dialogic engagement contributes to their process of mathematics learning during collaborative work, we explored the learning process of two 9th grade students transitioning to the deductive discourse while solving a geometric task. Drawing on commognition, we found that dialogic engagement contributed to students' learning in two ways. First, the students were able to correct their initial procedures; second, they were using their partner's initial procedure as a stepping-stone to the deductive discourse. Our findings suggest that growth in mathematical discourses in collaborative learning may necessitate a specific kind of dialogic engagement that requires students to be able to question the meta-rules at the basis of discourses, to be selective in the steps they adopt and to actively make necessary adaptations. This kind of dialogic engagement may enable students to make critical transitions bolstered with a sense of ownership and agency.

Keywords: Collaborative learning, dialogic engagement, deductive geometry, routines

Introduction

In the past few decades, studies have shown that collaborative mathematics learning can be effective and more conducive to learning than individual learning (e.g., Schwarz et al., 2000; Schwarz & Linchevski, 2007). In contrast, other studies have questioned this effectiveness (e.g., Ben-Zvi & Sfard, 2007; Chan & Sfard, 2020; Sfard & Kieran, 2001). This may suggest that only some cases of mathematics collaborative learning are effective. One aspect that has been suggested as key to the effectiveness of collaborative learning is students' dialogic engagement (Sfard, 2020; Wegerif, 2011). However, studies examining students' dialogic engagement concomitantly with their mathematics learning processes are rare. Consequently, we do not know much about the ways in which students' dialogic engagement contributes to their mathematics learning process during collaborative work. It is this that we aim to explore in this study. We pursue our goal by focusing on collaborative problem-solving in middle school geometry. This, since a particularly critical transition is required from students in those years – the transition to deductive geometric procedures. In this transition, students who are used to performing visual-configural procedures for substantiating claims (such as showing congruence by placing one triangle on top of the other) are required to shift to using new deductive procedures based on given data and geometric theorems (such as congruence theorems) (Duval, 1998). This transition has been viewed as most challenging to effective learning (Duval, 1998; Harel & Sowder, 2007).

Theoretical framework

The theoretical framework which we will use to pursue our goal is commognition (Sfard, 2008). Commognition is a sociocultural discursive framework which has been shown to be productive for studying interaction and learning concomitantly (Ben-Zvi & Sfard, 2007; Heyd-Metzuyanim & Schwarz, 2017; Sfard & Kieran, 2001), as well as critical transitions in mathematics learning (Lavie & Sfard, 2019; Sfard, 2007). The commognitive framework views repetition as the gist of learning and conceptualizes learning as a process of routinization of students' actions (Lavie et al., 2019). Routines - repetitive patterns of actions – are thus the commognitive basic unit for analyzing learning.

A routine is performed by a given person in a given task-situation (a situation in which the person considers herself bound to act). It is defined as "the *task*, as seen by the performer, together with the *procedure* she executed to perform the task" (Lavie et al., 2019, p. 161). For example, an instructor may create a task-situation by presenting students a geometric problem containing two triangles and asking them to show that the two triangles have the same area. Students may use different procedures (series of actions) for the same task. One student may use a visual/configural procedure of placing one triangle on top of the other and showing that they are "the same"; a second student may use a meta-arithmetic procedure of expressing the areas of both triangles using the triangle area formula and showing that they are equal; and a third student, may use a deductive procedure using congruence theorems. Moreover, the same student may use these different procedures in different stages of her learning. For example, a student using the configural procedure may, a year later, after learning congruence theorems, use the deductive procedure. The student's routine, in this case, would develop from including only a configural procedure to including two procedures: a configural procedure and a deductive one. By studying mathematical routines, commognitive studies were able to show such developments in children's learning (Lavie et al., 2019; Lavie & Sfard, 2019).

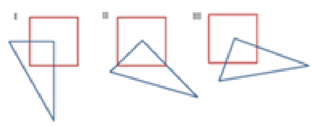
According to commognition, critical transitions, such as the transition to deductive procedures, are particularly challenging, since they go further than simply requiring students to shift from familiar procedures to new ones; they require a much more substantial shift – a shift between discourses (Sfard, 2007). A discourse is distinguishable by its routines and meta-rules. The configural and the deductive discourses are such distinguishable discourses. The configural discourse is based on the meta-rule that visual estimation is sufficient for substantiating claims. In contrast, the deductive discourse is based on the meta-rule that one must rely on data, axioms, definitions and theorems for substantiating claims, and that visual estimation is not sufficient. Such a conflict in meta-rules may create a difficulty when students attempt to transition from one discourse to another. To overcome this difficulty, students need to be dialogically engaged with the new discourse (Sfard, 2020).

Dialogically engaged students, according to Sfard (2020), show interest in their partner's discourse by: actively examining the possibility of differences between their discourse and that of their partner; acting as aspiring participants of their partner's discourse; and striving to fully individualize their partner's discourse. However, dialogic engagement with a new discourse is challenging in peer learning, since peer learning, by definition, often includes learners who are all novices in the new discourse (Ben-Zvi & Sfard, 2007). Students remain relatively novices in the new discourse even after exposure to the new meta-rules and often oscillate between the more familiar meta-rules and the less familiar ones (Sinclair & Moss, 2012).

In this study we focus on collaborative geometry problem-solving of middle school students, who are at this stage of oscillating between the more familiar configural meta-rules and the less familiar dedcutive ones. Drawing on Sfard's definition of dialogical engagement, we view dialogically engaged students as those showing interest in their partner's discourse, that is, in their use of words, visual mediators, narratives and routines. Based on this theoretical framework, we ask: how did students' dialogic engagement contribute to the development of their routines during collaborative work, particularly to the development of new deductive procedures?

Methodology

The participants of our study were 10 middle school students (six 8th graders; four 9th graders) who took part in a mathematical activity facilitated by the first author ("the instructor"). The design of the activity was based on videotaped lessons of the VIDEO-LM project (Karsenty & Arcavi, 2017) in which a geometric problem called *The three squares* was presented. The problem contained three drawings, in which identical right-angle triangles are placed in different orientations on top of identical squares (see drawings in Figure 1). The students in these lessons were asked to compare the shared areas in the three drawings. The canonical "correct" answer to the problem is that all the shared areas are equal. Based on these lessons, we designed a mathematical activity, which included: the presentation of the problem on the board; an individual work session in which students worked on a worksheet (see Figure1); and then a dyadic work session in which they collaboratively worked on the same worksheet.



1. In each drawing, color the shared area of the square and triangle
2. Line up the drawings according to the size of their shared area (from the smallest to the largest)
3. Circle the correct answer in each of the following claims and explain it:
   a. The shared area in drawing I is (smaller than /larger than/equal to/impossible to know) the shared area in drawing II
   b. The shared area in drawing II is (smaller than /larger than/equal to/impossible to know) the shared area in drawing III
   c. The shared area in drawing III is (smaller than /larger than/equal to/impossible to know) the shared area in drawing I

Figure 1. The worksheet

The individual session was designed to allow some access (albeit limited) to participants' initial routines before peer interaction, and to enable answering our research question regarding the development of their routines during peer interaction. Sections 2 and section 3 (and its sub-sections) were designed to allow students to return again and again to the same routine of comparing areas. To afford students maximal flexibility regarding their choice of procedures, the worksheet did not include any direct instructions on how participants should substantiate their claims (i.e., deductively). Additional data (i.e., the right angle of the triangle is located at the intersection of the square's diagonals) were given orally by the instructor upon request.

The activity was recorded by several cameras. Each pair had their own stationary camera and microphone; an additional camera was moving with the instructor. All five collaborative interactions were fully transcribed in a high-level resolution (i.e., gestures and facial expressions) and analyzed using footage from the different cameras. Students' ten individual worksheets and five dyadic collaborative worksheets were also collected and analyzed.

The analysis included first, analyzing students' individual worksheets (prior to peer interaction) and identifying their initial routines (task and procedure) for comparing the shared areas. Next, we analyzed students' peer interactions and identified their routines during these interactions. To examine students' development of routines during peer interaction – particularly, the development of new deductive procedures – we categorized the procedures of the students' routines (in individual session and peer interaction) into: configural; meta-arithmetic/configural and deductive (see table 1).

Table 1: Categorization of procedures

Procedure	Based on	Example
Configural	Visual estimation and manipulation of configurations	Visually estimating if shapes are congruent by placing them one on top of the other
Meta-arithmetic/configural	The use of formulas coupled with visual estimation	Employing an area formula in which the factors are visually estimated
Deductive	Given data, definitions, axioms, formulas or theorems	Proving that shapes are congruent by using congruence theorems, or employing an area formula in which its factors are based on the given

In addition, we analyzed students' dialogic engagement by identifying communicated interest in the partner's discourse, such as listening to partner's words, narratives and routines and attempting to clarify and examine them (e.g., "what do you mean by 'equal'?"; "what do you think?"; why do you think so?"), as well as looking closely at and examining partner's visual mediators (e.g., pointing at a drawing and asking "do you mean that triangle?").

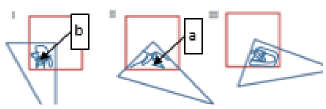
Findings

Our analysis, performed on all five collaborative episodes, identified only one episode containing a development of deductive procedures within the routine of comparing the shared areas. Full deductive proofs are being taught, according to the Israeli curriculum, only in 9^{th} grade. Therefore, the fact that deductive discourse did not appear in the three 8^{th} graders collaborative episodes did not come as a complete surprise. In what follows we focus on this one episode of 9^{th} grade students, containing a successful transition to deductive procedures. The two students participating in the episode were Orna and Tamara (pseudonyms), two relatively high achieving students, in a class which was on the highest mathematics track in their school. We begin by presenting the students' initial routines in their individual problem solving. We then present the ways by which dialogic engagement during peer interaction, contributed to the development and implementation of their routines.

Initial routines in individual problem-solving

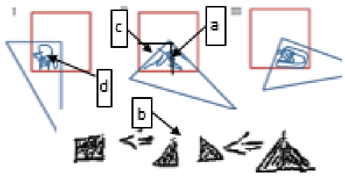
Analyzing Tamara and Orna's individual worksheets, we found that the two students used different procedures for the task of comparing the shared areas, none of which was deductive. Tamara used a configural procedure, while Orna used a meta-arithmetic procedure. These procedures resulted in different claims. Orna claimed that the shared area in drawing I is the smallest and the one in drawing II is the biggest (I < III < II), while Tamara claimed that the shared areas in drawings I and II are equal, and the one in drawing III is the smallest (III < II = I). Orna, in her explanation to the claim that I is smaller than II, wrote (in brackets: implied words and visual mediators; the squiggled figure to the right is used as a representation of visual mediators in worksheet after coloring the shared areas):

Because in order to calculate an area we need to multiply base by height, and because the triangle (a) in II has a bigger base (than the base in b), then I (b) is smaller than II.



Examining Orna's explanation to the claim that I is smaller than II as well as her written explanations to her other claims (III < II; I < III), we see Orna's procedure as including three basic steps: first, recalling area formulas ("multiply base by height"); second, visually estimating the relation between formula components in the two shared areas (equal heights; "II has a bigger base" than I); third, comparing the area formulas of the shared areas ("I is smaller than II"). Since Orna was basing her answer on her recollection of area formulas as well as her visual estimation of formula components, we categorized her procedure as meta-arithmetic/configural. The implementation of Orna's procedure was non-canonical (incorrect), since she was using the same area formula (base times height) for all shared areas regardless of their shape. Consequently, her resulting claim was non-canonical ("I is smaller than II"). In contrast, Tamara was basing her answer purely on visual estimation. In her explanation to her claim that shared areas I and II are equal, she wrote:

The (shared) area of drawing I is in a shape of a square, unlike the (shared) area of drawing II, which is in the shape of a triangle, so if we cut in half (a) the triangle of drawing II, we'll get two small triangles (b). We'll move one of the small triangles in order to get a square (c). The square we got is equal to the square in drawing I (d). (Tamara's visually mediated meanings are reconstructed in the top figure. Her written illustrations appear below).



Tamara's procedure included: first, dividing the shared areas into parts (arrows a and b); second, moving the parts from one place to another (arrow c) to form similar-looking areas (in this case, similar looking squares); and third, visually comparing the formed areas. Tamara was thus using a configural procedure based only on visual estimation and manipulation of shapes. Her implementation of this procedure resulted in the claim that the shared areas in drawings I and II are equal, and the one in drawing III is the smallest. Both girls thus arrived at the peer interaction stage with non-canonical, yet differing claims. Moreover, they were using different procedures to support their differing claims, none of which was deductive. Figure 2 presents side-by-side Orna and Tamara's routines in individual work. As seen, Orna and Tamara's procedures did not include even one step in common.

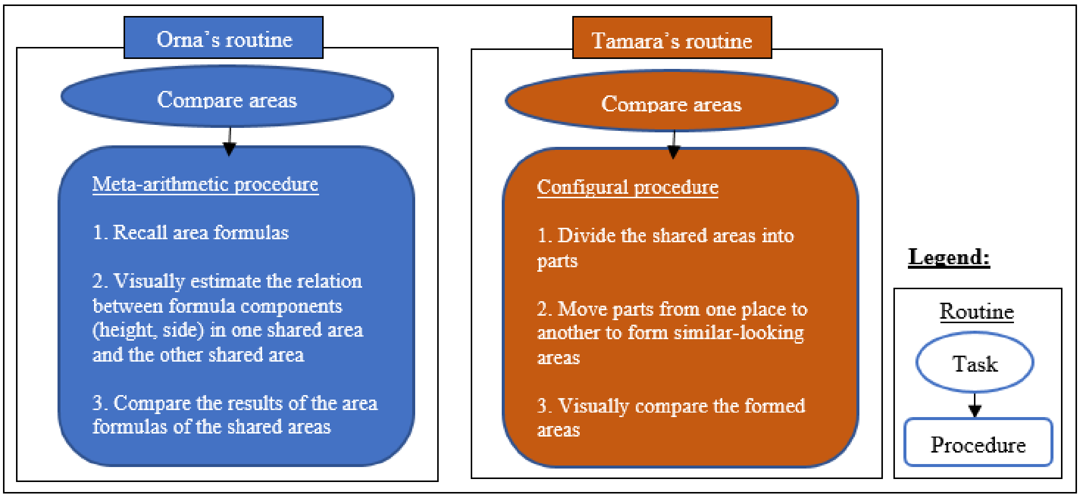


Figure 2. Students' initial routines in individual work

Contribution of dialogic engagement to the development of routines

Analyzing Tamara and Orna's collaborative session, we found that both students were dialogically engaged with each other's discourse at different times during the episode. Their dialogic engagement contributed to their learning in two ways. First, students were able to correct previous non-canonical implementations of their own initial procedures. Second, while the initial routines in individual session included only configural and meta-arithmetic procedures, the developed routines included new deductive procedures. In what follows, due to space constraints, we illustrate these developments by focusing only on Orna; yet, similar developments were found in Tamara's case.

Correcting implementation of one's own initial procedure

Orna and Tamara's peer interaction followed their individual session and thus began with the aforementioned differences between their solutions both at the level of their claims (Orna: I < III < II; Tamara: III < II = I) and at the level of their procedures (Orna: meta-arithmetic; Tamara: configural). The students noticed their differences right from the start of their interaction. Tamara responded to these differences by explaining her answer to why I is equal to II and presenting her configural procedure, as can be seen in the following excerpt.

Excerpt 1: (Implied words); [overlapping speech]; (n*on-verbal gestures/signals)*

No.	Speaker	What is said	What is done or pointed at
26	Tamara	So I said that, like, the area of I (a) is equal to the area of II (b)	27	orna	O.k. (I'm listening)	
28	Tamara	Cause like, if you cu… imagine that you are cutting this triangle (a) in half	29	Orna	Ahha (I'm listening)	
30	Tamara	And then you move one of the triangles (to place a), so like its … you get the same square (as b)	31	Orna	Ah so this (a) is equal to that (b)?	32	Tamara	Yes, that's what I think	
33	Orna	And this (a) is bigger than them (shared areas I and II) or smaller than them?	34	Tamara	Amm (*not sure, smiling*), this needs ah… cause think as if this (a) is, say, the same area square (as b), so like you need to calculate this area (c)… (her voice is fading)	35	Orna	It looks to me like this (shared area III) is [bigger]…	
36	Tamara	[Ah like] (*takes the sheet*), imagine, then, this part (a) (*draws a line to base*), o.k.? the one here (*strengthening the line she drew*) is like a supplement to this area (b) (meaning, the left triangle (a) can be moved to place (b) to form a square similar to the one in shared area I)… (*looking at the drawing*)… but I got that they are equal! (laughs, touches Orna's elbow, covers her mouth)	37	Orna	Ah (*smiling, leaning forward, focused on the drawings*), they supplement, ok, but look, there is here, it's like a square and there is another triangle here (a)… Actually, it looks to me like they are all equal (*examining the drawings, nodding her head*).	
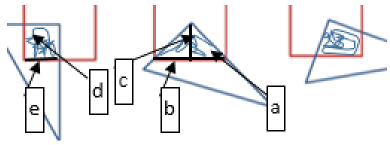
38	Tamara	That's what it is, that's it	
39	Orna	They're all equal (*decisively*, *leaning backward*), let's write that they're all equal	

Examining excerpt 1, we can see that Orna was dialogically engaged with Tamara's discourse. She listened to Tamara's explanation of her configural procedure (27, 29); clarified Tamara's narratives (31, 33); examined Tamara's procedure and questioned it (37); and all the while looked closely at the relevant visual mediators (the parts to which Tamara referred to in the drawings). By leaning forward, focusing on the drawings, and examining Tamara's visual mediators (pointing at small triangle (a) in line 37), it seems that Orna was trying to implement Tamara's procedure (with her eyes). At first, she seemed uncertain about it ("ok, but look…"), but after examining the drawings she decided that all shared are equal (37, 39). The word "actually" (37) coupled with her decisive tone when stating that all areas are equal (39), suggest that she had some kind of conviction in her newly endorsed claim and a sense of ownership. When the students turned to write their explanation, Orna said, “and like each one (of the claims) we explain…according to the ‘supplement’”. The word “supplement” first appears in line 32, when Tamara is explaining her configural procedure. Orna’s use of Tamara’s word signifies that she was suggesting that they use Tamara’s configural procedure. However, when Tamara suggested that they write what she had written in her individual sheet (the configural explanation), Orna said:

65 Orna Amm… Ok, so I’ll write that like here (a), that’s a triangle (shared area II), so you do: base (b) times height (c) and divide by two. Here (d, shared area I) you don’t divide by two. That’s (b, base of shared area II) is double the size (of e, base of shared area I).



Despite seemingly adopting Tamara's procedure, Orna reverts in line 65, to her previous meta-arithmetic procedure. Interestingly, she made no indication of her suggestion being different from Tamara’s configural explanation (such as “ok, but…” or “let’s do it this way”). On the contrary, her "Ok, I'll write", which followed smoothly from the conversation, masked the sudden return to her previous procedure. We interpret this masking of disagreement in two ways. First, it may be Orna’s quiet way of confronting disagreements. Alternatively, it may indicate that Orna was perceiving her suggested procedure as sufficiently similar to that of Tamara, or at least as drawing on Tamara’s suggestion. Indeed, Orna’s suggestion in line 65 was *not* an exact replica of her initial procedure; this time she was suggesting a canonical (correct) implementation. Rather than assigning the same formula to all shared areas as she had previously done, here Orna distinguished between the shapes of shared area II and I and consequently between their area formulas. Therefore, Orna changed her implementation of the first step of her meta-arithmetic procedure: the recollection of area formulas.

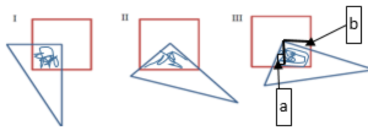
The change seems to have resulted from Orna’s dialogic engagement with Tamara’s discourse in two ways. First, Orna’s previous endorsement of Tamara’s claim that “all areas are equal” (39), seemed to have made her realize that “all areas are equal” should *also* be the resulting claim of her previous meta-arithmetic procedure. This made her examine her own initial procedure and correct it. Second, Tamara’s distinction between the two shapes of shared areas I and II (square and triangle) may have helped Orna realize what needs correction in her initial implementation, that is, that she was using the same formula for different shapes. Therefore, Orna’s dialogic engagement with Tamara's procedure contributed to the development of her own routine by improving the implementation of her initial meta-arithmetic procedure.

<u>Developing a new procedure based on partner’s procedure</u>

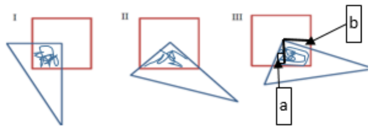
A second development in Orna’s routine occurred toward the end of the interaction when the students discussed why shared area I and III are equal. This time, Orna did not only adopt Tamara’s claim (that I=III), but also drew on the steps of Tamara’s configural procedure to suggest a new deductive version of this procedure. The following excerpt begins with Tamara suggesting again to use the configural procedure for comparing III and I:

<u>Excerpt 2:</u>

132 Tamara … you need to say that, like you move this part (a) to here (b) and then like [it will form a square]

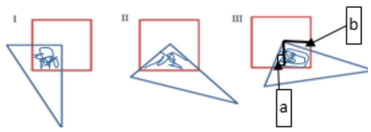


133 Orna [I have an idea], if we, like, show congruence (between) this (a) and that (b), then… (meaning: by showing that these triangles are congruent, they can show that their areas are “the same”)



…

141 Orna No, no look, you need to say that this (a) is like (meaning congruent to) this (b) in order for it to be ok to move the…



In line 132 Tamara repeated her configural suggestion to move part (a) so that it covers part (b) and form a square similar to the shared area in drawing I. In response to Tamara’s suggestion, Orna proposed that they use congruence theorems to substantiate that the areas of the triangles (a and b) are the same (“I have an idea, if we, like, show congruence" [133]). In line 141, Orna further explained that in order to claim that triangle (a) can be moved on top of the triangle (b) in a way that exactly covers it, they need to show that they are congruent ("you need to say… in order for…"). In other words, she did not agree ("no, no…") with the meta-rule of the configural discourse that visual estimation is enough. Rather, she drew on the configural procedure to develop it into a deductive congruence procedure. Therefore, Orna's dialogic engagement with Tamara's procedure contributed to the development of a new procedure in Orna's routine.

Figure 3 presents Tamara's configural procedure next to Orna's new deductive procedure. As can be seen, Orna adopted the three steps of Tamara's procedure. However, her new deductive procedure does not end with the last step of Tamara's initial procedure. Rather, it includes an additional final deductive step of substantiating the visual comparison using congruence theorems (step 4). This development is obviously a product of Orna's dialogic engagement with Tamara's discourse, since the basis of Orna's new deductive procedure is Tamara's configural procedure. It was only through following the steps of Tamara's procedure, that Orna adopted the claims, that the two triangles (a and b) are the same and that shared areas I and III are equal. The *adoption* of these claims, coupled with Orna's *non-adoption* of the meta-rule of the configural discourse, seem to have led Orna to come up with the "idea" (133) of using congruence theorems.

To summarize, examining Orna's dialogic engagement, it is clear that she did not simply adopt Tamara's procedure. Rather, there seems to be a gradual process of ownership of Tamara's procedure. First, Orna adopted Tamara's claim that all shared areas are equal; second, she reverted to her own initial procedure and corrected it; third, she adopted steps of Tamara's procedure; and forth she added a final deductive step to Tamara's procedure.

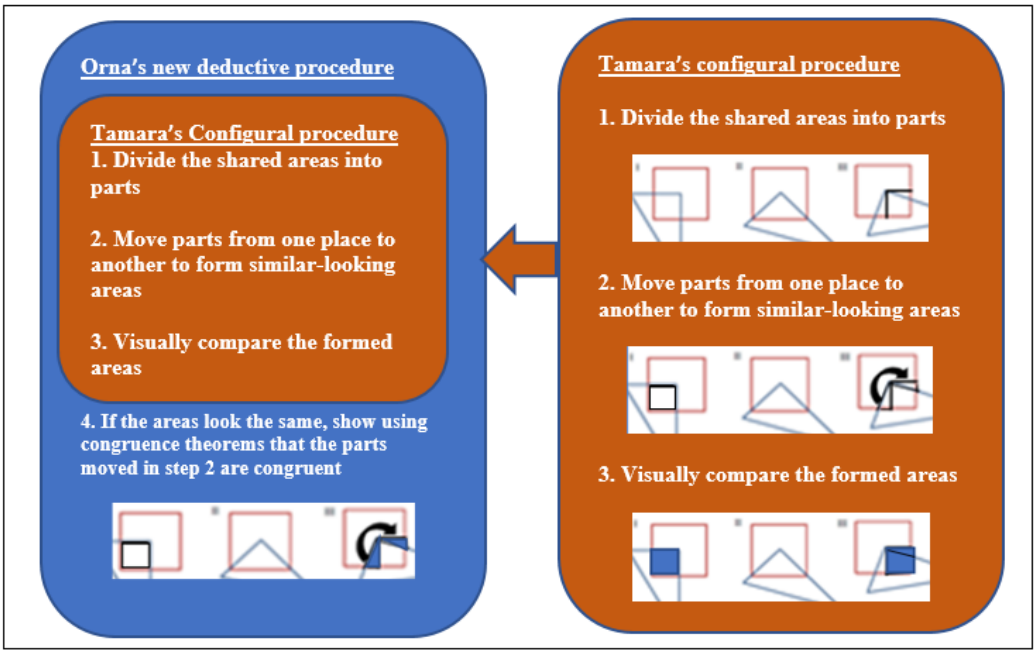


Figure 3. Orna's new deductive procedure built on Tamara's initial configural procedure

Discussion

Our goal in this study was to explore the ways in which students' dialogic engagement contributes to their process of mathematics learning during collaborative work. We pursued our goal by analyzing commognitively an effective collaborative geometry learning episode of two 9th grade students. We found that the students' dialogic engagement contributed to their learning in two ways. First, the students were able to correct previous non-canonical implementations of their own initial procedures. Second, the students were using their partner's initial procedure as a stepping-stone to the deductive discourse. This kind of growth in mathematical discourses during collaborative learning stands in contrast to previous studies showing mainly lack of growth in discourses during collaborative learning (Chan & Sfard, 2020; Sfard & Kieran, 2001). Our study, thus, not only supports the argument that collaborative mathematics learning can be effective and more conducive to learning than individual learning (e.g., Schwarz et al., 2000; Schwarz & Linchevski, 2007), but also shows *how* students' dialogic engagement can contribute to students' transitioning to more developed discourses. Rather than adopting their partner's procedure as is, students drew on their partner's initial procedure to suggest a deductive new procedure. Our findings may explain why growth in mathematical discourses is so rare in collaborative learning. It necessitates a specific kind of dialogic engagement that does not satisfy itself with listening and adopting the partner's discourse. Rather, it requires students to be able to question the meta-rules at the basis of discourses, to be selective in the steps they adopt (whether consciously or not) and to actively make the necessary adaptations. Our study suggests that this kind of dialogic engagement may enable students to make critical transitions bolstered with a sense of ownership and agency.

Designing for Compassion in Schools: A Humanizing Approach to Co-Design

Ashley Seidel Potvin, Leah Peña Teeters, William R. Penuel

University of Colorado Boulder

Abstract: Collaborative design as a participatory approach to organizing research and learning environments engages educators as partners in ways that draw on their lived experiences and identities (Bang & Vossoughi, 2016). This paper focuses on the co-design of a course for educators in compassion and dignity and explores co-design as a humanizing experience for educators, one that invites educators' whole selves into the process. We ask: a) *In what ways is the co-design of a compassion course a humanizing experience? b) How does a humanizing co-design process support the enactment of compassion across scales of practice?* The intentionality given to the co-design experience supported participants to see connections among meetings, professional contexts, and personal lives in new and expansive ways. As participants enacted learning across scales of practice, they were presented with new understandings of the content, and in turn designed a product that embodied expansive and compassionate learning.

Keywords: co-design, humanizing, compassion, expansive learning, educators

Introduction

Collaborative design, often referred to as co-design, as a participatory approach to organizing research and learning environments, engages educators as partners in ways that draw on their expertise, lived experiences, and identities (Bang & Vossoughi, 2016). Co-design processes can be both challenging and rewarding for educators as they explore new and unfamiliar roles and content (Frumin, 2019; Penuel, Roschelle, & Shechtman, 2007; Potvin, 2020). In this paper, we address Ehret and Hollett's (2016) call for attending to the "lived dimensions of learning and being that are just as essential to lasting, transformative change" (p. 251) within participatory design, which they argue have been overlooked. Specifically, we explore what we refer to here as the *humanizing* aspects of co-design, that is, the ways that the co-design experience is characterized by compassion and individual and collective agency for reimagining new possibilities for schools. A humanizing co-design environment is one that recognizes the complexity and multidimensionality of all participants, and where dignity and care are centered (Camangian & Cariaga, 2021; Paris, 2011).

The co-design project presented in this article was focused on the design of a digital compassion course for educators that addresses the essential dignity of educators and students, supports the wellness of educators through compassion practices and tools, and contributes to educators' capacities to imagine and create more just and compassionate schools. We define compassion as the recognition of another person's suffering coupled with a response to relieve that suffering (Ashar et al., 2016). Compassion can be practiced, cultivated, and sustained through specific training and community contexts that provide individuals with tools and resources to reduce the distress they feel when faced with another's suffering and increase their ability to respond (Jazaieri et al., 2014; Weng et al., 2018). Key elements include extending compassion to people perceived as difficult, investigating obstacles to extending care to them, and recognizing that everyone is deserving of compassion (Jinpa, 2015). Cultivating compassion has the potential to support educators and researchers to work toward equity and justice, and counter deficit views of students and families that often permeate schools (Cammarota & Romero, 2006; Conklin, 2008).

We analyze a co-design project focused on a novel context where educators and researchers had varied familiarity with the core content (compassion practice), specifically, where expertise was distributed across the research-practice boundary and variable across the whole team, and where there was significant uncertainty about how to link individual practices of compassion to the shared design goal of supporting collective action toward more equitable, just, and compassionate schools. We argue, through analysis of educators' perceptions and experiences, that the co-design process was a humanizing experience for educators involved. We examine the ways that the humanizing co-design process invited expansive learning across multiple scales of practice and in turn, how this impacted the designed product.

Theoretical framework

Co-design for expansive, humanizing learning depends on creating conditions for people to learn together, and to envision ways not just to develop personal insights but also to support collective action toward more just and compassionate schools. Expansive learning theory posits that learning occurs as "learners are involved in constructing and implementing a radically new, wider and more complex object and concept for their activity" (Engeström & Sannino, 2010, p. 2). It is an apt theory for analyzing co-design for compassion, as participants engaged in the design of a radically new compassion course for educators.

A key feature of expansive learning is that the content or skill is not predetermined. That is, the design or solution to a dilemma is not specified in advance, rather, the collective works together to develop novel designs and approaches. Learning occurs as people collaboratively develop solutions, such that co-designers learn together from creating, as they bring expertise to the experience that gets transformed in the process of designing something new. Through a facilitated process of co-design, new activity is created when participants negotiate and solve problems together and new possibilities emerge. It is through the process of forging new forms of activity and designs together that opportunities for transformative agency are ripe. Through the expansive learning process, these new forms of activity and design "carry future-oriented visions loaded with initiative and commitment by the learners" (Sannino et al., 2016, p. 603).

Transformative agency is not just an important indicator of the expansive learning process, it is also central to our conceptualization of humanizing design environments. Our notion of humanizing co-design is rooted in frameworks for compassionate organizations (Dutton et al., 2006) and expansive learning (Engeström & Sannino, 2010), which emphasizes that co-design experiences should recognize that members are more than their professional identities, encourage members to display their full humanity, care for one another, and support individual and collective agency in imagining radically different possibilities for their organizations. We draw upon these key features of compassionate organizations in our analysis.

In our analysis, we investigate the ways that humanizing approaches to co-design support expansive learning (Engeström & Sannino, 2010) across scales of practice. Expansive learning engages the entire activity system in which participants are situated, producing new forms of activity and possibilities for meaningful participation. From an activity theory perspective, where the collective ecology of activity is considered, the aim of co-design for compassion involves shifts in not only individual practices, but also a reorganization of ways of participating across scales of practice (Jurow & Shea, 2015). Generating learning that can be applied across physical, social, and temporal scales requires approaches to design that move from the individual level of change to systems level of change. We analyze the ways that co-design facilitation and participation supported a systemic approach to learning and design.

Methods

Our primary research questions are: a) *In what ways is the co-design of a compassion course a humanizing experience? b) How does a humanizing co-design process support the enactment of compassion across scales of practice?*

Co-design context

The co-design project was focused on the design of a digital course on teacher leadership in compassion and dignity. The goal of the course was to provide educators with resources for caring for themselves and cultivating and sustaining compassion for students, students' families, colleagues, and their school communities. Co-designers consisted of ten educators from a partner school district and five university-based researchers. Educators included teachers, counselors, and one principal from six elementary and middle schools. The team met weekly in-person for two hours between October 2019 through May 2020, for a total of 58 hours. We catalyzed our collaboration with a "bootstrapping event" (Penuel et al., 2007); the team of educators and researchers completed an 8-week compassion training together focused on the growing science of compassion and secular practices for cultivating compassion grounded in the Buddhist tradition. This experience served to establish a shared foundation and framework for compassion that informed the co-design process and the designed course. The team then met weekly in person until March 2020 when the COVID-19 pandemic resulted in statewide stay-at-home orders, and meetings moved to a virtual platform until May 2020. Meetings focused on applying compassion practices to support wellness, analyzing sources of suffering in schools, and designing content for a compassion course.

Data sources

We collected and analyzed data from 13 co-design meetings, including audio transcripts, fieldnotes, and artifacts created or modified during meetings (e.g., curriculum planning documents). In addition, we collected written educator reflections and we interviewed educators at the conclusion of the study using a semi-structured interview protocol.

Data analysis

Using qualitative methods, we developed a codebook by identifying deductive codes from our conceptual framework. We used Engeström and colleagues' (2014) approach to analyzing transformative agency in deductive coding to look for the ways in which educators demonstrated agency throughout the co-design process, coding for *resisting*, *criticizing*, *explicating*, *envisioning*, *committing to action*, and *taking consequential actions*. We also drew upon the compassion organizing framework (Dutton et al., 2006) in our deductive coding to surface when a school routine or policy was mentioned, a participant recounted a story of care, or named an emotion they experienced, and to explore how it is participants navigated moving from individual practice to collective action to transform their schools. The first two authors then coded two meeting transcripts together using the deductive codes and developing additional codes inductively, revising the codebook (Miles et al., 2014). The first two authors coded several transcripts individually until inter-rater reliability was established at 90% and then continued until all data were coded. They wrote analytic memos, summarizing emergent themes. The first author then engaged in second-cycle coding to consolidate codes and identify salient themes. They continued writing memos to summarize the themes and shared them with the other authors for review. Key themes were discussed among the author team and checked against the data corpus.

Findings

Within the co-design work, participants shared meals, discussed vulnerable experiences, engaged authentically with a wide range of emotions, and shared stories of their families. Participants were invited to bring their full selves to the collaborative process and to the curriculum design. Through bringing their full selves to the process, the team co-constructed a humanizing design environment that opened possibilities for agency, compassion, and imagination. This fostered a reciprocal form of engagement, whereby participants demonstrated agency, contributed to the co-design process, and engaged in new learning that they brought into other contexts (e.g., classrooms, schools, parenting). As co-design supported movement across scales of practice, the designed course thus embodied that same spirit to move beyond overly individualistic paradigms of compassion towards a more collective paradigm.

Co-design as humanizing

The co-design experience bridged personal and professional aspects of educators' lives

The team completed an 8-week compassion training and subsequently engaged in compassion practices together during co-design meetings. Educators shared that such practices had become integral to both their personal and professional lives. The compassion co-design supported them in developing a home compassion practice, in which they engaged in informal (e.g., bringing awareness to a daily routine) and formal (e.g., contemplative meditation) practices. As Jessica explained, "What we're talking about here [compassion practice] in terms of being a tool for teaching, this kind of bridges that gap of the personal development that becomes professional development" (Jessica Interview). In Jessica's view, the co-design experience and the compassion course designed offered skills beneficial to both her personal and professional life. The invitation to examine one's personal *and* professional life and to apply compassion practice in both contexts was a unique experience for Jessica. Educators used the compassion practices to deepen their relationships with friends and family members, such as their children, and they used these practices to improve their interactions with colleagues, students, and students' families who they viewed as challenging. In reflecting on her experience of the compassion training, Ruth highlighted the ways that the co-design experience bridged both personal and professional elements of her life. She shared that the training

> really affected me in a great way. Because I was starting from a baseline of not having a practice. So, the only place I could go is up. And the whole idea of understanding and really thinking about how we all have our moments of suffering and we're all really doing our best. It's not that that wasn't anything that I was aware of but just brought it to a new level of awareness and understanding for me. So that was really important. And I noticed that I was really in a more grounded place all Fall. Just really did affect me which carried over to my parenting, which carried over to my interactions with colleagues and my work with students, my understanding. (Ruth Interview)

For Ruth, engaging in compassion practices and establishing a routine of these practices marked new learning for her. She underscored the importance of learning about compassion and compassion practices, which impacted her parenting and relationships with colleagues and students and supported her to feel more grounded personally and professionally.

Several educators highlighted that they developed tools for self-compassion through the co-design process; self-compassion moved across social scales as educators applied these tools to their personal and professional lives. Self-compassion was an important design and discussion topic as the team worked to develop a compassion curriculum in the midst of the onset of the COVID-19 pandemic. The group often engaged in self-compassion practices and discussed both challenges to and tools for self-compassion. Bridgette, for example, spoke about how challenging self-compassion was for her, sharing that it was

> kind of the source of all my stress and, you know, teachers staying up at night just worrying about kids. It's all because we feel such a strong responsibility for, you know, all of these students. And we feel emotionally connected to them and it just can be like a really strong emotional toll and leads to that kind of burnout thing. And I think self-compassion is the first step and really dealing with that, and the more we kind of talked about that I saw how important that is for educators. And it's been really meaningful to me and helped me be better and more compassionate to my students when I am able to give myself a break and just not be in this obsessive thinking and worrying about how I'm perceived, or things like that. It's really a transformational thing, I think. (Bridgette Interview)

Bridgette, like other educators in the group, gave insight into how self-compassion was essential for her personal and professional wellness, sharing that when she learned to be more compassionate towards herself, she was able to demonstrate more compassion towards her students. For Bridgette, this was a profound and even "transformational" experience, and one that was deeply embedded within the humanizing co-design process.

Designing the compassion course was authentic and meaningful

Educators in this study experienced co-design as a process that supported their personal and professional development and wellness and reciprocally recognized that their personal and professional experiences were essential for developing the compassion curriculum. During meetings, educators shared both personal and professional challenges which helped shape the design of the compassion course. Mia, who shared on several occasions that she had been experiencing a challenging year, recognized that many other educators may feel similarly and thus her struggles were important to bring to the design: "my stress as an educator was so heightened that I could engage in the thinking of designing a course … I'm in it. I can really speak to burnout. I can really speak to stress from this very real currently lived experience" (Mia Interview). Educators not only recognized the importance of their lived experiences to the design, but also viewed one another's contributions as essential. Michael explained that team members "each had potent contributions to the whole and this in turn makes me have a ton of confidence that the end result will be accessible to all who choose to take the course" (EOY Reflection).

A couple of educators did not immediately recognize the expertise they brought to the process, but as they continued to show up, they gained more confidence in themselves and in the process. At the end of the year Ruth reflected that she was most proud that she "work[ed] through my anxiety that I wasn't going to be able to bring anything to the group or offer anything to the group because I was starting at a place where I wasn't sure about any of it … What can I offer? … But finding that the collective work and the collective energy and the collective conversations, everybody was able to add to it" (Ruth Interview). Both educators who expressed uncertainty about the process continued to attend meetings consistently and made significant contributions to the course design, suggesting that they, as Ruth stated, found support in the "collective work" and "energy."

For many educators, developing a compassion course with and for other educators was authentic and meaningful. At times, educators referenced the future students of the course and facilitators often encouraged the group to consider these future students in the design. Educators viewed the co-designed compassion course as a shared mission, one that "is going to try to bring more good into the world" (Bridgette Interview).

Co-design fostered connection and a sense of rejuvenation

Educators described the co-design process as one that fostered connection and rejuvenated them, suggesting that the environment was a humanizing one for educators. Educators found that connections forged through the co-design process served as an antidote to feelings of isolation. Feelings of isolation are prevalent in teaching (Schlichte, Yssel, & Merbler, 2005), and such feelings were exacerbated by the context of the global pandemic. Bridgette shared that

> One big takeaway from the codesign process was a strong sense of community. I can feel isolated sometimes in my job and it was amazing to work with so many people who have the common goal of bringing more compassion into the world. Especially in this time where there are so many things to be depressed about, this really restored my faith in humanity and helped me realize what is important in life and in my job. It helped to hear that others struggle with very similar situations in the educational world. I saw immediate impacts in my day-to-day life and my work. It has helped me bring a sense of compassion to every interaction with parents, students, and even my own family. (EOY Reflection)

Bridgette found comfort and connection within the co-design "community," and these connections offered her a different perspective on "humanity," her "life," and her "job," one that was hopeful and agentic. This in turn bolstered her to bring compassion to her school community.

Bridgette was not the only educator who felt buoyed by the co-design process. Nora described the meetings "like a support group every week for me" (EOY Reflection). Jessica explained that it "really reconnected me with kind of the ideals of teaching. I think the farther you get into your educational career, it can be so easy to be overwhelmed and kind of crushed by the minutiae of teaching that this was a nice re-centering for me in that personal and professional overlap" (Jessica Interview). Likewise, Mia explained,

> The co-design process has offered an opportunity to commit, to show up again and again, to work through resistance, to cultivate conscious and intentional community, and to finally rest in the nourishing comfort of a compassionate space with myself and with others. This process has been life-changing in that it has brought consistent mindful practice into a space that is usually so full and stressful. This process has transformed me, bringing self-compassion into a place that is often full of self-criticism. All of this allows me to step into my role as educator with more awareness and the ability to have compassion for others. (EOY Reflection)

For these educators, working together towards a shared goal of designing a compassion course for other educators with a vision of creating more compassionate schools, rejuvenated them, increased their hope, and prevented feelings of overwhelm and burnout.

Learning across scales of practice

A humanizing approach to co-design supported educators in applying and integrating learning across multiple scales of practice, including social, geographic, and temporal scales. While not a requirement of the co-design process, many educators practiced compassion outside of the meeting times, connected practices to their personal lives, and brought compassion into their schools, thus learning moved across scales of practice. It was this movement that helped the team begin to bridge between individual practices and changing schools in the design of the compassion course.

Educators reported engaging deeply in the inner work that supports compassion in action. For instance, educators spoke about being metacognitive about their emotions, changing the ways they reacted to situations, recognizing the suffering of those around them, and increasing self-compassion. Educators also identified particular practices that supported them to be more compassionate, such as bringing awareness to daily routines and interactions, setting intentions, and focusing on breathing during challenging situations. In several cases, educators already established a mindfulness or compassion practice prior to joining the team and these educators pointed to the co-design process as strengthening their practice.

Educators did not just keep compassion practices to themselves, but they also brought compassion into their own schools and relationships. Examples include teaching intention-setting and breathing practices to students, talking to colleagues and administrators about compassion, and using compassion tools to shift interactions with students, students' families, and/or colleagues who they considered challenging. Similarly, several educators reported bringing ideas from the co-design process into their schools — such as when one principal shared research articles with his staff that the co-design team had read together or when an educator began writing field notes, a practice that a subset of the co-design team engaged in, to reflect on her interactions at school. And, as we reported previously, educators applied compassion practices in their personal lives, using these tools to improve their interactions and relationships with family members and friends.

A key challenge for the design of the compassion course was to connect individual insight to collective action leading to change in schools. Facilitators situated design work within participants' school-based contexts and introduced readings/frameworks that sought to historicize and socialize suffering (e.g., Dutton et al., 2006; Garza, 2009; Ginwright, 2018). While shifting from individual insight to collective action in design was challenging, some members "got really excited" about the pivot to collective action and challenged others to accept responsibility for social and educational inequities by designing for more radically inclusive schools. Educators also began taking up compassion to shift structures and routines by engaging in actions such as starting staff meetings with a compassion practice, coaching colleagues who felt overwhelmed from the rapid transition to online teaching at the onset of the COVID-19 pandemic, and examining and revising grading practices. Further, educators discussed routines or policies in their schools and district that would benefit from change through a collective and compassionate approach, such as discipline, teacher evaluation, standardized testing, supports for students experiencing trauma, professional development, and classroom-level routines. Educators also identified existing practices in their schools as compassionate such as supporting student-led initiatives (e.g., student-organized school walkout for climate change), adjusting classroom discipline policies to work with students to develop a positive culture rather than removing students from the classroom, organizing a donation drive among faculty for personal and home items students in the school community needed (e.g., snow boots, kitchen items), and checking in with students more frequently through email and phone calls during remote learning due to statewide stay-at-home orders.

Cultivating a co-design environment that invited participants to bring their full selves was instrumental in supporting practices of compassion to be infused across multiple scales of practice. The approach centered the experiences of participants, supporting them to connect the learning to their personal and professional lives. As participants enacted new learning in diverse social settings, in varied physical spaces, and over time, the lens by which they understood compassion became oriented towards collective change of systems.

Designed course embodied co-design principles

The humanizing co-design process invited learning across scales, impacting the design of the compassion course. As educators engaged in expansive learning across multiple scales of practice, it made available novel forms of participation that expanded the possibilities for what could be designed. Educators brought their personal and professional lives to the co-design experience and demonstrated agency by taking new compassion ideas and practices back into their personal and professional spheres. These new experiences helped to inform the design of the compassion course as one that bridged individual practice and collective action. Ruth highlighted that the course was designed to support educators in establishing a personal compassion practice as well as to engage in compassionate action that moved across social and geographic scales. She explained, "this is a class that introduces and deepens one's understanding of compassion and the way that compassion is helpful on an individual, collective and global manner" (Ruth Interview).

Mia described the compassion course as unique, one that will impact educators' personal and professional lives: "It's just a personal shift in the way you live and see life that impacts everything. But definitely how you show up in the classroom, how you view your colleagues and parents and students. The entire learning community. It's an inside-out job…And that's what I think makes it really unique." She continued to describe the impacts of the designed course, "It's like this ripple out effect. You start with yourself and your understanding of all this and your lived experience and then it ripples out to impact the community, and hopefully if you're able to really bring in that leadership piece, impact your school staff and leadership. So that actually ripples out even further" (Mia Interview). Educators, like Mia, recognized the significance of designing a course to support other educators in learning across scales in a "ripple out effect;" one goal of the designed course was to support future educators taking the course to bring compassion and leadership to their school communities.

Some educators understood the compassion course to address professional challenges they experienced, such as a "stressful, results-driven culture in education" (Bridgette EOY Reflection) or "how we treat each other and treat ourselves" (Nora EOY Reflection). Jessica, for example, described the compassion course as addressing a sense of isolation and fostering a sense of connection.

> Teaching can be so isolating that I think this is a great tool for teachers in those moments of isolation. In those moments of losing your temper with a class, and those moments of staying awake at night suffering over "What do I do with this kid?" This is an excellent tool for teachers to have when they are just with themselves. So much of teacher professional development is "What can I do? How can I change this?" And this is just about "How am I, how do I be?" I've never had that addressed in education. And yet those ideas of staying awake at night of really emotionally investing are core. (Jessica Interview)

Jessica believed that the co-designed compassion course will help act as a bridge between educators' personal and professional lives, as it focuses on educators' wellness and addresses educators' relationships. Attending to the principles of compassion in the co-design process and not just the product changed how participants experienced co-design and in turn, generated a designed product that embodied the design principles more fully.

Implications

We sought to understand the ways that educators and researchers engaged in the co-design of a course to support educators to create more compassionate schools, and how they created a co-design space that centered humanizing interactions. Members brought their personal and professional joys and challenges to the co-design process. This authentic engagement encouraged educators to participate as their whole selves and supported connection and rejuvenation, informing the design of the compassion course and supporting co-design team members to carry practices of compassion across scales of practice. Educators felt confident to enact compassionate changes within their schools and personal lives and designed a curriculum that could support future educators to do the same. This study underscores the importance of attending to the process of co-design and experience of participants and suggests that doing so supports expanding participants' learning and experiences and generates designs for learning that are more powerful and sustaining. This study points to key structures that allowed for and encouraged a humanizing co-design environment to develop and offers practical suggestions for facilitators of collaborative design teams.

Reposition expertise through shared learning

A fundamental aspect of co-design holds that members of the design team bring their own knowledge, expertise, and experience to bear on the design (Penuel et al., 2007; Bang & Vossoughi, 2016). With the intention of repositioning researchers and educators so as to genuinely elevate the unique expertise of all team members, we engaged in shared learning. We participated in an 8-week course, where all participants were positioned as learners. The intentionality of designing experiences, such as participation in this course, where participants could learn together, share their knowledge, and expand their understandings was critical in the generation of humanizing co-design. We suggest that before embarking on a collaborative project, facilitators take stock of who holds expertise and power and plan for shared learning experiences to reposition participants.

Cultivate a community of care, compassion, and trust

The goal of the course promoted reflexivity and explicitly attended to prefiguring caring relationships within the co-design process that reflected how we hoped educators would engage in their schools. We integrated compassion practices into our weekly co-design sessions. Engaging in the compassion training and practicing compassion together supported the group in cultivating a community characterized by care, compassion, and trust and in developing shared language, goals, and experiences to build upon during co-design work. This foundation supported the enactment of compassion in the co-design space.

Center shared experiences of joy and suffering

Attention to context was essential for humanizing the co-design process, and this included explicitly acknowledging and making space for current global, personal, and professional events that impacted people's lives and caused both joy and suffering. The COVID-19 pandemic erupted in the midst of the co-design process, and it became a shared experience of suffering, one in which opportunities for compassion among our team arose. As meetings shifted to virtual and occurred in the context of participants' homes, pets and children became a regular part of meetings, in a way that invited joy and connection. There will always be events impacting co-designers' lives and providing opportunities for these realities to emerge within the process allows for fluidity of design, resulting in a product that continues to be responsive to the context and honor teachers' humanity.

Conclusion

We examined the ways that the humanizing co-design process generated expansive learning across multiple scales of practice. The intentionality given to the experience of co-design supported participants in engaging in the meetings, their professional contexts, and personal lives in new and expansive ways. As participants enacted their learning across scales of practice, they were presented with new understandings of the focal content, and in turn developed a designed product that embodied expansive and compassionate learning. Our analysis underscores that researchers and facilitators must attend to the process, not just the product, of co-design. To support the design of humanizing experiences, researchers and facilitators can (1) reposition expertise through shared learning, (2) cultivate a community of care, compassion, and trust, and (3) center shared experiences of joy and suffering.

Abstract: The objective in the current paper is to examine the processes of how our research team negotiated meaning using an iterative design approach as we established, developed, and refined a rubric to capture comprehension processes and strategies evident in students' verbal protocols. The overarching project comprises multiple data sets, multiple scientists across (distant) institutions, and multiple teams of discourse analysts who are tasked with scoring over 20,000 verbal protocols (i.e., think aloud, self-explanation) collected in studies conducted in the last decade. Here, we describe the iterative modifications, negotiations, and realizations while coding our first subset comprising 7,559 individual verbal protocols. Drawing upon work in design research, we describe a process through which the research team has negotiated meaning around theory-driven codes and how this work has influenced our own ways of conceptualizing comprehension research, theory, and practice.

Introduction

Learning from text involves a negotiation of meaning between multiple entities, including authors, instructors, and students. Students are often faced with the challenges of understanding and learning from text that exceed their prior domain knowledge and reading skills (e.g., Goldman & Bisanz, 2002; Moje & Speyer, 2014). Through a more robust understanding of these learning processes, researchers can develop activities and interventions that can help students to better learn from the challenging texts that they encounter. Thus, we aim to understand the various constructive processes that learners use when building and negotiating the meaning of texts. In our work, our overarching goals are to understand these processes and to develop adaptive technologies that provide individualized support for students as they learn from text.

One approach to understanding readers' comprehension processes is to have them produce verbal protocols as they read. Students may be asked to "think aloud" by reporting whatever thoughts come to mind. They may also be asked to "self-explain" in which they explain the text to themselves as they read. Prompting students to generate these verbal protocols as they read can be a means of enhancing learning, but such prompts also serve as a window through which researchers can better understand the processes that students engage in when they read (e.g., Chi, 1997; McNamara, 2004; Pressley & Afflerbach, 1995). Coding and quantifying these responses allows researchers to examine how different processes and strategies relate to students' individual differences (e.g., interest, prior knowledge, reading skill; e.g., Coté et al., 1998) and to learning outcomes (e.g., Magliano et al., 2011) as well as response to interventions (McNamara, 2004).

For the past few decades, members of our team have gathered approximately 20,000 verbal protocols in our various studies of learning from and with text. Our current objective is to code (or recode) these reader responses using a common rubric agreed upon by an interdisciplinary group of researchers and discourse analysts.

Qualitative approaches lend a rich understanding of discourse (e.g., Gee, 2014; Pressley & Afflerbach, 1995). To attempt to scale these approaches, many researchers quantify qualitative aspects of discourse to statistically relate these features to other factors such as individual differences or experimental variables (e.g., Chi, 1997; Coté et al., 1998). This coding process relies on rubrics designed to capture a theoretical construct of interest and reaching reliability between raters (Chi, 1997). Typically, a rubric is designed by scientists or experts, and raters adapt their codes to increase reliability, iteratively matching to the conceptual rules set by the expert and to each other. The rubric is more or less the stable entity, wherein examples are added and some wordings may be modified, but few substantive changes are made. In some cases, discussions can lead to non-trivial refinements in how the constructs are conceptually and operationally defined, but this seems rare, or at least opaque. The debates, discussions, and decisions surrounding the operationalization of constructs (if they occur) are generally left unreported when the main objective is to reach quantifiable reliability between raters. In many papers, this complex process is often distilled down to a single sentence (e.g., "*raters were trained to criterion and then coded the remainder of the data*").

Our objective in the current paper is to examine the *process* of how our research team negotiated meaning as we established, developed, and iteratively refined a rubric to capture these important comprehension processes. We describe a negotiation of meaning, but one different from that faced by the readers - one underlying the process of coding these protocols: a negotiation between the scientists (who developed the rubric) and the discourse analysts tasked with reaching agreement in their assessments of the nature of the processes revealed within the protocols. We examine how these interactions resulted in a deeper understanding of the student responses and the larger research goals.

The current project

There are two unique aspects of the current project. The first is its scope and scale. In most situations, a few hundred verbal protocols are scored by a pair or a small group of raters who are co-located and the data are coded within a small window of time. Our project, by contrast, included multiple data sets, multiple scientists across three (distant) institutions, and multiple teams of discourse analysts. Moreover, due to COVID-19, these negotiations have occurred predominantly in virtual space. A second unique aspect of this project was exploring the development and refinement of the rubric as both an iterative design task to create a functional educational tool and a learning opportunity in and of itself.

While the larger research project draws from cognitive theories of text and discourse comprehension (see McNamara & Magliano, 2009, for a review), the current work around the development and refinement of the rubric takes inspiration from both instructional design and design-based research. Although agreed-upon definitions of design-based research remain elusive, central considerations of DBR is that research is iterative, collaborative, and highly sensitive to its context (e.g., Barab, 2014). Of particular interest in the current work is the way in which expert researcher/scientists and novice rater/discourse analysts co-constructed meaning within small rating teams and across the larger project as they worked through the coding process. Establishing reliability often requires in-depth discussion about which codes are relevant to the research question and how those codes are operationalized. Modifying the rubric requires mutual understandings between the scientists and the discourse analysts. We iteratively adapted the rubric and our mutual understandings to increase not only reliability between the raters, but also to capture the unique perspectives of the raters. This "push and pull" between reliability and validity, wherein one objective is to maximize reliability between raters, and the other is to maintain some level of validity intrinsic to the fundamentally qualitative nature of the analysis, was a driving force in this process.

Context and data sources

The larger project relies on verbal protocol data from a series of large-scale studies. These data were collected from different regions of the US, included students reading at, above, and below grade levels, native and non-native English speakers, and students enrolled in both traditional college courses and those assigned to developmental education. Although the texts and tasks varied from study to study, the general procedure for collecting verbal protocols was the same. Students read a text and were prompted to type a verbal protocol at various target sentences (predetermined locations in which connections and explanations were likely to be fruitful for comprehension). Such typed protocols are easier to collect than spoken protocols and yield similar properties in terms of the strategies that readers demonstrate during reading (Muñoz et al., 2006). Some protocols were produced under the instruction to think aloud while others were instructed to self-explain. This varied both within and across studies. After reading and generating verbal protocols, students answered either multiple-choice or open-ended comprehension questions. In addition to the comprehension task, students also completed a variety of individual difference tasks including standardized comprehension tests, foundational reading skills tests, and various measures of interest such as working memory. In some studies, verbal protocols were collected in a single session, while in other studies, the verbal protocols were collected before and after reading comprehension interventions. The research team included four experienced researchers (the PI and Co-PIs of the project) and two teams of graduate students and research assistants spread across multiple research sites. A third team was brought into discussions, but due to practical limitations, especially in light of COVID-19, this team left the project. However, we wish to acknowledge their contributions to our thinking and the various revisions to the rubric.

In the current work related to the design and iterative refinement of the coding rubric, we relied on multiple data sources. We collected copies of each iteration of the rubric (including tracked changes and comments from version-to-version). The raters coded the verbal protocols in excel spreadsheets. Raters were asked to provide their codes as well as any notes or questions they had regarding specific responses. Thus, we had these excel files for each rater's initial independent pass and a second pass "corrected" after discussion. We also had combined excel files in which we compared rater scores and logged discussion notes. Additionally, we examined rater and researcher notes from the weekly meetings that occurred during initial training as well as email threads that include discussions around specific examples.

Design cycle

This work was inspired by instructional design (e.g., Silber, 2007) and design-based research (Design Based Research Collective, 2003; Easterday et al., 2014). This paper reflects our initial design cycle from preliminary problem conception through a first implementation, evaluation, and refinement of the coding rubric. Critically, in addition to the larger "design loop", we also focus on important rapid, iterative cycles that occurred throughout the process. These cycles involved both quantitative and qualitative analysis of the rubric and inter-rater agreements. Our design cycle appears in Figure 1. In the following sections, we outline each phase of the research in more detail to describe the process and how the discussions within rater groups and across the larger team led to refinements in the rubric as well as the team's understanding of the theoretical underpinnings and implications of the codes.

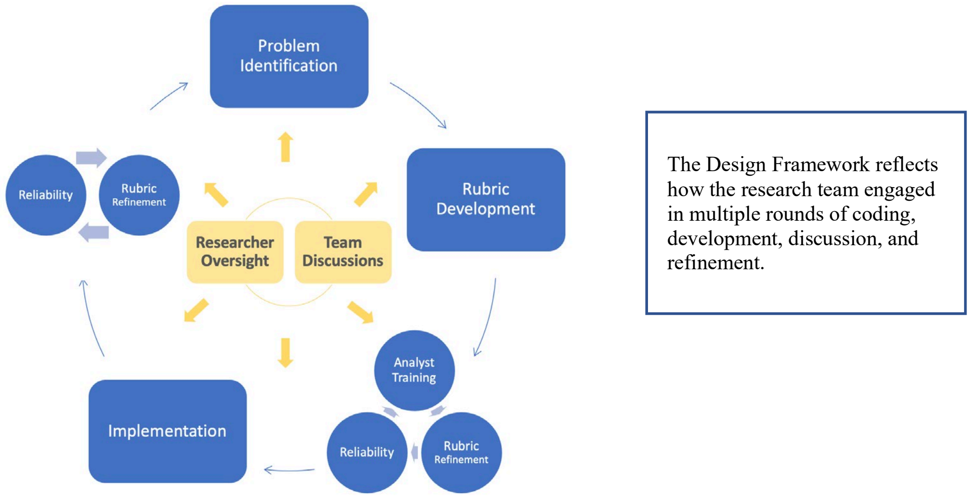

Figure 1. Design Framework

Phases 1 and 2: Problem identification and rubric development

Although these data sets have been scored by human raters in previous studies, the protocols have been scored by a number of different raters using similar, but not identical rubrics. Thus, in order to be able to draw meaningful conclusions and to make comparisons between datasets, the research team agreed that we needed to develop a common rubric. While our team has expertise in quantified qualitative protocol analysis, the scope of this project brought to light interesting theoretical and practical issues. Our data sets include different age groups and skill levels, different types of texts (history, science), reader tasks (e.g., self-explain, think-aloud), and different methodological aims across studies. Thus, we were tasked with developing a rubric that was (1) sensitive to different texts and tasks, but general and *flexible* enough to be applied across a number of contexts and (2) reflected strong enough criteria (e.g., rules) for consistent operationalization, but not so rigid that the codes no longer reflected authentic human judgments.

Our ideation process revolved largely around developing an initial rubric. Our initial rubric was adapted from a number of extant rubrics that have been designed based on theories of discourse comprehension (see McNamara & Magliano, 2009). These theories assume that readers engage in a number of comprehension processes and strategies that support the construction of a coherent and elaborated mental model. The rubrics used in this area of research tend to include three broad categories of strategies: paraphrasing, bridging, and elaboration. *Paraphrasing* is a process in which students reproduce content from the texts. *Bridging* is a process of establishing how the current sentence is related to prior discourse context and provides the primary basis for achieving coherence in a mental model. Finally, *elaboration* is a process that involves integrating information from prior knowledge with information provided by the text. Bridging and elaboration are *inferential processes* that are critical for mental model construction. It was also important to us, theoretically, to not categorize each protocol as *either* paraphrase, bridging, or elaboration, but rather the extent to which these processes were apparent in students' protocols. Thus, our rubric included three broad dimensions: presence of the strategy, nature of the strategy, and an overall quality score. Table 1 shows the questions that each of the codes were designed to address. Additional codes were included to capture other common behaviors (e.g., inaccurate statements, life events, direct copy and pasting).

Table 1: Questions driving the three dimensions of interest for paraphrasing, bridging, and elaboration

Dimension	Paraphrase	Bridging	Elaboration
Presence of Strategy	How much of the target sentence is captured? *(none; some; most)*	To what extent is information from previous text present? *(none, little, some, much)*	To what extent does the reader bring in outside information to make sense of the text? *(none, little, some, much)*
Nature of Strategy Use	-	Are connections made to ideas in previous sentence (*local bridge*) or other previous sentences (*distal bridge*)?	Is the outside information relevant to understanding the text?
Overall Quality	What is the overall *quality* of the response? *(Poor, Fair, Good, Great)*		

Phase 3: Training and rapid iterative refinement

The initial data set (Magliano et al., 2020) included verbal protocols from 597 college students. Students wrote verbal protocols for two texts. The history text (Louis XVI) included six think aloud locations and the science text (Erosion) included seven think aloud locations. In total, the data set comprised 7,559 individual verbal protocols. The verbal protocols were left segmented "as is" in the sense that the totality of what a student wrote in response to a given target sentence was coded as a single response.

We randomly selected a subset of 20% of the verbal protocols for training and refining the rubric. This subset of protocols was randomly selected at the participant by text level and then divided into three training phases. The research sites engaged in both intra-team and inter-team discussions. Given time constraints, Team 1 was working full time, while Team 2 was working part time. Raters were encouraged to make notes in the coding files and to bring issues to group discussions. Evaluating and discussing common disagreements led to additions and refinements to the rubric. Major modifications included: a) the addition of a metacognitive *monitoring* code reflecting occasions when students expressed clarity or confusion, b) addition of codes that reflected the nature of a students' paraphrases (*lexical change*, *syntactic change*), c) the simplification of an *accuracy* code from four levels to a dichotomous *misconception* code, and d) modifications of language related to presence and quality of elaborations.

After the third round of coding to obtain reliability, Team 1 demonstrated good reliability on overall (0-3) score (k = .71) and the presence scores (paraphrase presence = .74, bridge presence = .73, elaboration presence = .77). Reliability estimates on the nature of the verbal protocols scores were often lower, but acceptable (syntactic change = .64; lexical change = .81; bridge contribution = .73, elaboration relation = .64). Additional codes (e.g., too short, copy/paste) ranged from .73 to full agreement.

Phase 4: Implementation

Once the first team of raters had established sufficient reliability, the remaining responses were divided amongst the raters, with a random set of 10% of their total assigned responses for post hoc reliability calculations. The raters sent their scores at the end of each week. Coding this data set took approximately 4 months to complete (with some delays due to COVID-19). At the same time, the second team was continuing to establish reliability and to confer with the first team about ongoing disagreements. There were no major changes made to the rubric during this time.

Phase 5: Evaluation and refinement

In most projects, coding the remainder would reflect the "end" of this process. However, given our overarching objective to understand the nature of the protocols, we continued into a second phase of evaluating reliability. Once the first team of raters completed scoring the data set, we examined reliability across the randomized overlap to explore rater drift. The reliability calculations illustrated that most codes were markedly lower than the initial benchmarks, with overall score k = .46 and other scores ranging from k = .48-.73. In order to identify systematic inconsistencies between the raters, we used confusion matrices to identify common mismatches across the raters. Table 2 shows a confusion matrix for the presence of paraphrasing for one of the training phases. The diagonal (green) shows where raters agreed, and the other cells indicate discrepancies. The confusion matrices allowed the research team to identify systematic differences across raters (indicated here in red). These instances became the basis for discussion that led to insight into the construction of meaning by students and is reflected in the rubric.

Table 2. Example confusion matrix for paraphrasing.

		Coder 2		
		0	1	2
Coder 1	0	116	20	0
	1	5	50	7
	2	1	10	98

Examining confusion matrices also revealed that elaboration had become overgeneralized to include *any* information that could not be found in the text and that this had resulted in inflated overall scores for statements that were unrelated to the semantic content of the text. Through discussion across the teams of raters, it was agreed that *elaboration apparent relation* code would be removed and to instead add a more general *nonsense* code to capture statements that were *irrelevant* or off-task. There was also an addition of an *evaluative statement* that seemed to emerge frequently in the history text. These statements tended to follow an "x should have done y" format. While such responses are on task, they did not align with notions of paraphrase, bridging, or elaboration in ways exhibited by other types of statements. As a result of these discussions and changes to the rubrics, raters' reliability increased on *elaboration presence* from k = .48 to .80 and the new codes showed good reliability (evaluative = .74; irrelevant = .83; monitoring = .78).

Lessons learned

Examination of our rubrics and meeting notes (as well as discussions related to the development of this paper) revealed a number of important lessons that we carry forward into our next cycle of refining and implementing this rubric on the next set of data. Our lessons-learned span issues pertaining to the construction of meaning, sensitivity to contexts, the iterative process of refinement, and how consideration of this task as design work led to important insights and valuable changes to our research more broadly.

Negotiating and co-constructing meaning

There were inherent challenges in developing operational definitions that allowed coders to draw upon a shared understanding of the processes of paraphrasing, bridging, and elaboration. These challenges included the negotiation of the underlying meaning of various constructs and the operationalization of these constructs.

Negotiating constructs

The co-construction of knowledge occurred in the context of differences in disciplinary knowledge, epistemological perspectives, and experience coding protocols for both the research scientists and coders. This occurred even in the context of the senior researchers on this project who have an extensive history of collaboration, share a common theoretical perspective, and have implemented similar coding protocols over the past 20 years (e.g., Best et al., 2004; Kopatich et al., 2019; Magliano et al., 2011; McNamara, 2004). While there was a shared understanding of the constructs delineated in Table 1, there were non-trivial differences in how they have been operationalized across studies. For example, both Magliano et al. (2011) and McNamara (2004) used rubrics that were intended to identify the presence of elaboration. However, Magliano et al. (2011) did not evaluate the extent to which elaborative processes reflected the process of knowledge building, whereas McNamara (2004) advocated sensitivity to identifying the role of elaboration in support of knowledge building. These differences were revealed in the early stages of refinement and training of coders, but required several rapid iterations to uncover. The lack of common ground on this issue was only discovered with intense qualitative discussions on coding disagreements between separate teams. These discussions laid bare not only gaps in our rubric, but also helped the researchers to co-construct the meaning of these definitions and how they related to comprehension processes.

Negotiating operationalization

There are tensions inherent to transforming qualitative natural language into quantitative scores. One objective is to reach reliability between raters. This process requires constructing a well-defined rubric, with examples and rules. There are two particular tendencies that we have observed. These two stances toward the coding task became apparent to us because one team of analysts approached this task from one direction, while the other team approached it from the other. On one side, we observed a tendency for raters to seek absolute rules and guidelines, (e.g., exact number of words necessary to qualify as a paraphrase, number of words beyond the target sentence qualify as an elaboration). We have found it challenging to convince coders that humans will have disagreements, but if one relies solely on 'counting' words, the element of human judgment is lost (i.e., we might as well have a computer count words). On the other side of the continuum, coders sometimes "read into" protocols rather than basing judgments on the explicit content of the protocols. Such a tendency is natural because we cannot stop the activation of our own prior knowledge. Thus, coders make inferences using their own knowledge while coding. However, the coders sometimes expressed notions that the student producing the protocol should be "given credit" for an attempt. This was particularly true for protocols that were relatively short (e.g., *Erosion are bad.*), had mechanical and grammatical errors that made them difficult to understand, or were ultimately idiosyncratic (e.g., *Too much water isn t [sic] also good for crops people and mostly, Houston. it floats every time it rains so the people are mostly homeless*.). As a consequence, there emerged a propensity to identify the presence of more sophisticated learning strategies than those reflected in the explicit content of the protocols. Establishing agreed upon ways of scoring protocols required our team(s) to reevaluate and refine their understanding of the task writ large and its role in addressing the larger research question.

At the same time, emergent and persistent disagreements led us to reconsider our constructs. For example, our original coding scheme included four levels (0-3) of elaboration presence. Raters indicated that they were able to clearly understand the difference between a 1 (one or two *words* from outside the text) as compared to 2s and 3s (*ideas* from outside the text). However, they struggled to discern a 2 (an idea from outside the text that is vaguely conveyed) from a 3 (an idea from outside the text that is complete and clearly conveyed). As a result, we collapsed 2 and 3 into a single code that reflected any idea from outside the text. This inability to achieve reliability brings into question the extent to which this distinction is construct-relevant or theoretically important.

Multiple aspects of context

Those who have written about quantified qualitative analysis (e.g., Chi, 1997; Vogel & Weinberger, 2016) note that context is an important consideration for evaluating discourse. In our work, we further identified the need to consider multiple contexts simultaneously.

Tensions between sentence context and participant context

The purpose or quality of a given protocol is context dependent and each protocol exists within multiple contexts. For example, the protocol *Erosion are bad* is, in comparison to other reader responses, relatively poor in quality. However, this protocol nested within a struggling reader's other protocols, may reflect a breakthrough or at least preliminary evidence that the reader is making some sense of the text. Our different coding teams adopted different preferences for sorting and coding the protocols. Some of our raters found it easier to code protocols linearly by student. That is, the rater would code Student A's protocols in response to target sentences 1-9 before coding Student B's responses. These raters indicated that the context in which the student made the utterance helped to make sense of the students' intended meaning in ambiguous responses. By contrast, other raters found it easier to code by target sentence, such that they would code target sentence 1 for Students A-*n* and then code target sentence 2. These raters found that the comparison across multiple students talking about the same sentence made the distinctions between codes more apparent. Both approaches have obvious advantages. However, the end result was that the different approaches resulted in different ratings. Our solution was to adopt aspects of both. Our current approach is to first code by participant to leverage the knowledge that the moment-to-moment context provides. Once the rater has scored a number of participants (e.g., at the end of the week), the rater resorts the data file by target sentence, examines their own intra-rater reliability, and makes changes based on any discovered inconsistencies.

Tensions between operationalization and generalizability to text context

Our data sets include different texts from multiple genres, including science and history. Thus, our texts vary not only in terms of task, but also in terms of content, genre, and text-specific features. The operational definitions in our rubric needed to be broadly conveyed so that they could be reliably applied to multiple types of texts. This led to protracted discussions regarding text and sentence-specific patterns that impacted how students expressed their thoughts. For example, both texts within the training corpus included cause-and-effect relations. However, responses within the history text included comments about "character" intentionality, which were not evoked within the science texts; and vice versa, science texts evoked particular phrases and sentence structures that were not present in the history texts. These differences forced us to reconsider the extent to which a statement was semantically-related and relevant to the broader context of the text. Such concerns have led us into continuing discussions regarding the extent to which these processes are similar or different across tasks, contexts, and genres and what these differences say about comprehension more generally.

Iterative refinement within a larger design-based framework

The final set of insights pertained to the benefits of our design loop. The multiple rapid cycles of discussion and refinement without the larger design cycle were particularly helpful in a project of this scale. As illustrated in Figure 1, we have emphasized rapid cycles of evaluation and refinement at multiple points throughout the coding process. This flexibility in approach has allowed us to quickly respond to concerns and adjust to issues as they emerged. Those who are well-versed in instructional design and design-based (implementation) research are aware that these processes occur and can be crucial to the success of an intervention. However, cyclical, reactive iterations are often not considered within the context of coding verbal protocol responses.

In most verbal protocol coding projects, the objective is to capture the target construct, but the focus is on establishing and maintaining reliability between coders. Once reliability has been achieved, there is little consideration of how changes that may have occurred during training influence the larger project. By checking our reliability during the implementation phase, we were able to identify stark drops in reliability, which forced us to consider the ramifications of the issue, including its theoretical implications. Discussions amongst the team highlighted the value of the quantitative data as a means to drive qualitative understandings. The quantification of discrepancies between coders provided a basis for discussing how constructs were defined. Frequent use of reliability metrics and confusion matrices allowed us to more quickly identify and diagnose points of disagreement, confusion, and misconception. These quantitative metrics afford a valuable way to engage in rich discussion, allowing the team to be more responsive to issues of both reliability and validity as coding continued.

By contextualizing this work within a design cycle, we were able to capitalize on the notion of "closing the loop" (e.g., Liu & Koedinger, 2017). In much design work, tools and systems are built, deployed, and evaluated, but many fall short of subsequently capitalizing on the discoveries made during evaluation to improve the design moving forward. Closing the loop refers to making sure that the data derived from one evaluation is used to inform the next cycle of problem identification. In light of increased cross-institutional collaborations and the growth of large-scale and big data, framing coding procedures as design work affords a way to structure the development and refinement and, perhaps most importantly, the documentation of the iterative nature of rubric development. We continue to use these methods of discussion and iterative refinement as we progress through additional data sets. One question that remains for us is the extent to which it is appropriate and feasible to reopen closed loops. That is, as we progress through our data sets, to what extent might we revisit "completed" data sets when we have a new discovery that changes our rubric. We continue to consider these implications, including their costs and their benefits.

Conclusion

Learning scientists and educational researchers more broadly often rely on rubrics and inter-rater reliability to identify and evaluate learning processes and behaviors. Through exploring our own process of iterative development and refinement, we observed critical tensions between theory and real-world implementation, as well as reflexivity regarding our own assumptions about comprehension processes. We encourage those who engage in these types of coding tasks to similarly step back from the process and flexibly respond to breaks in the coding process as opportunities for knowledge co-construction and negotiation of meaning.

Abstract: Debugging is an important skill all programmers must learn, including preliterate children who are learning to code in early childhood settings. Despite the fact that early learning environments increasingly incorporate coding curricula, we know little about debugging knowledge in early childhood. One reason is that the tangible programming environments designed for young children entail a layer of material complexity that we have yet to account for in terms of learning to debug. In our study of young children learning to program, we found that in the midst of solving programming tasks and learning to debug, tangible toys presented bugs of their own. This paper analyzes video of Kindergarteners learning to debug errors in the program and errors in the physical materials. We argue that concurrent physical and programming bugs present opportunities for young children to learn about the broader computational system in which they are learning to code.

Introduction

Debugging is known to be an important programming skill (Pea, 1986; Pea et al., 1987), and studies of debugging are seeing a resurgence in the learning sciences (DeLiema et al., 2020; Fields et al, 2016; Brady et al., 2020; Kafai et al., 2020). While much of this work deals with the knowledge and computational thinking of novice programmers, there has been less emphasis on how very young children learn to debug. Despite the fact that early learning environments increasingly incorporate coding curricula and CS standards, we know little about programming and debugging knowledge in early childhood (Wang & Choi, 2020). One reason for this gap is that language-dependent frameworks for debugging do not necessarily apply to preliterate programmers. The novel programming environments designed for young children entail a layer of material complexity that we have yet to account for in terms of learning to debug.

Rather than screen-based environments like Logo (Papert, 1980) or block-based tools like Scratch Jr., preschool and Kindergarten children frequently use tangible and hybrid coding toys (e.g. Bers, 2018; Horn, 2018). These types of programming tools include components that can be shared amongst a group of early learners, supporting collaborative debugging activities (Fields et al., 2016). They also introduce a number of new issues for collaborative work, because the materials are distributed and manipulable. Often, in the midst of solving programming tasks and learning to debug, tangible toys present bugs of their own. In this paper, we refer to these types of issues as "physical bugs," and we examine how children reconcile solving bugs in the domain of the program with concurrent bugs in the physical, material domain.

First we review how physical materials have been treated in studies of debugging, drawing a through-line between Papert's (1980) floor turtles and today's tangible toys. Next we briefly describe our design-based study of Kindergarteners learning to code using robot coding toys. We present our analytic process and initial findings that discriminated between buggy problems with the *program* and buggy problems with the *physical materials*. Then we illustrate what resolving these types of bugs looked like when they occurred in isolation and then concurrently, during a series of debugging tasks that a group of Kindergarteners worked to solve in the course of a 30-minute lesson. We show how the objects they used to resolve the coding errors introduced bugs of their own, and we highlight how children debugged both orders of problems. We argue that, rather than constraining or complicating children's debugging skills, tangible toys present opportunities for children to learn about the larger coding frame or system in which programming occurs.

Framing perspectives: Tangible coding toys and young children's debugging

Papert's (1980) floor turtle was one of the first tangible coding toys. Prior to the standard screen-based Logo version, children programmed the turtle to draw basic shapes using a pen that was fitted to its body. Although the floor turtle was more practical for connecting young programmers to the physical world, the robots were expensive, and few made it out of MITs Media Lab and into Kindergartens (Bers & Horn, 2010; McNerney, 2004). No longer tethered to the computer and now increasingly affordable, today's coding toys bear some resemblance to the first turtles. A growing suite of tangible programming robots can be found in early learning settings (Yu & Roque, 2018).

Describing how children resolved errors in turtle programming, Papert (1980) wrote that "the process of debugging is a normal part of the process of understanding a program" (p. 61). Commonplace as debugging may be among novice programmers, we do not yet have an understanding of what the process of debugging looks like for young children. Some early tangible programming tools that grew out of the Media Lab, such as Perlman's Slot Machine, required children to re-code entire sequences rather than editing buggy programs (McNerney, 2004), a fairly inefficient strategy when the program grows to more than a few commands. In his studies of young children programming in Logo, Pea (1986) referred to a "superbug," the idea that, independent of programming language, novice programmers learn that some meanings need to be expressed explicitly in code, while others do not. Already hardwired, beyond the programming domain at the level of electronics, lies another layer of encoded problems to solve, black-boxed within the robot the children are programming (Resnick et al., 1998; 2000). For young children, debugging using tangible toys involves solving problems at the level of the program and at the level of physical materials (Fields et al., 2016).

Study design: Coding in kindergarten

This study took place in the context of a larger design-based research project called Coding in Kindergarten (NSF #1842116) where we are investigating early childhood computational thinking using commercially available robot coding toys (Clarke-Midura et al., 2021). Participants were 48 children in 3 schools, divided into groups of 3-4 children for coding lessons. Lessons occurred twice per week for one month, and children were assessed following implementations. Coding lessons were designed to elicit knowledge and skills associated with computational thinking (i.e. algorithmic thinking, sequencing, pattern recognition, decomposition, and debugging). During lessons, groups of children and a teacher interacted with a series of tangible robot coding toys and other materials included in the coding kits, such as large floor grids used for planning robot paths. Lessons involved programming a robot to travel on a path through the grid, and "codes" consisted of directional arrows placed in a sequence of movement commands. The tangible programming environment- color-coded directional commands, large floor grids, and multiple manipulatives- supported groups of preliterate children to build and debug programs.

The focal cases in this paper illustrate children's interactions with Botley, a coding robot that operates by entering directional codes into a remote control connected to the agent through Bluetooth (see Figure 1). Botley's kit comes equipped with a set of directional arrow tiles that can be sequenced to build a program. Botley can be used with or without its "arms," which guide a small ball into a goal. We observed that it was sometimes difficult to keep the kit's directional arrow tiles in order when sequencing algorithms, thus we iteratively designed means of organizing the codes, making them easier to manipulate. In the first two cases, children used magnetic code tiles on a metal sheet to build their program. In the third case, they built programs using the code tiles that came equipped with the coding toy kit, along with a paper program organizer designed by members of our research team. One minor detail, important for Botley's operation and for interpreting the cases, is that you must press the "trash" button on the remote control to clear Botley's program before programming and executing a new one.

Data and analytic methods

Approximately 30 hours of classroom coding lessons were video recorded and then content logged (56 individual lessons) (Jordan & Henderson, 1995). We then conducted qualitative coding, which consisted of iterative rounds of open coding for characteristics of bugs and debugging activity followed by axial coding according to an emergent relationship between (1) bugs in the program and (2) problems with the materials (Glaser & Strauss, 1967). Within these two broad categories, we identified types of bugs/problems and strategies for resolving/repairing them, and we conducted frequency counts. Further analyzing patterns in frequency and occurrence of bugs, we found that, rather than discrete bugs solved serially, programming and physical bugs frequently co-occurred. For this paper, we selected two cases that illustrate what it looked like when children only needed to address a programming or a physical bug and contrasted these with a third case of a 30-minute lesson which elicited multiple co-occurrent bugs. We conducted interaction analysis of these debugging episodes, focusing on participants' talk, gesture, and coordinated use of materials (Jordan & Henderson, 1995).

Frequency of bugs and strategies for resolving/repairing

Table 1 summarizes the results of the types and frequencies of bugs and strategies for debugging in both the program and bugs related to physical errors (i.e., physical domain). Overall, bugs in the program most often involved turn errors and missing codes, and errors related to the materials most often involved controller errors. Students' strategies were frequently related to the type of bug. For example, if the students' program was missing a forward code and the robot did not make it to the goal (i.e., *Missing Code*), the debugging strategy was usually to *Add on to End*. In the cases below, while we mention the strategies students used, we focus our analysis on the ways students addressed programming and physical bugs. Case 1 illustrates a situation in which students encountered a *Wrong Start Code* bug (programming bug), and Case 2 provides an example of an *Initializing Robot* bug (physical bug). We use Case 3 to illustrate students' ways of resolving and repairing multiple concurrent bugs.

Table 1: Bug types and strategies for Programming and Physical bugs

PROGRAMMING BUG TYPES: semantic errors when specifying code sequence
Turn Errors (56) *Misunderstanding turn unit (turn-rotate, not turn-turn) or specifying opposite direction*
Wrong Start/End/Middle code (23) *Positional bug errors requiring switch at location in sequence*
Missing Code (63) *Children skip a code or miscount a number of needed rotations or forward moves*
Spurious Code (29) *Inserting or specifying an unneeded, extra code or codes*
Sequencing Error (9) *All codes are present, but out-of-order*
Goal/Path Problem (36) *Losing track of path being sequenced or lack of clarity about endpoint*
DEBUGGING STRATEGIES: process of diagnosing and resolving semantic errors
Swap Codes (46) *Removing a code or codes and replacing them with other codes*
Remove/Add on to End (76) *Editing the end of the program by making the sequence longer or shorter*
Clear Program, Start Over (30) *Removing all codes from the program board and/or pressing delete button*
Remove Code, Move Codes Down (10) *Shortening the program by removing a start or middle code error*
Accommodate Bug (9) *Transform a bug into a feature of the program, change the goal or path*
PHYSICAL BUG TYPES: physical errors in material or mechanical apparatus
Material Mishap (24) *Incidental issue with grids, tiles, or accessories (i.e. robot wheel snags on rug)*
Initializing Robot (38) *Forgetting to reposition robot on start position; false start; mis-orienting robot*
Controller Errors (130) *Remote control, program board (i.e. incomplete button press; forgot to "trash" out)*
Mechanical Issues (35) *Problems with motor, batteries, Bluetooth pairing, or on/off buttons*
Building in a Bug (29) *Intentional user error for pedagogical or personal reasons (i.e. sabotage)*
REPAIR STRATEGIES: process of operating and repairing physical errors
Halt and Re-run Program (56) *Interrupting program execution when a physical bug is identified, restarting*
Work-arounds (12) *Swapping out robot units or materials that are malfunctioning*
Just-in-time Fixes (18) *Catching, mitigating an issue with the physical apparatus before it causes a problem*
Sweeping a Bug under the Rug (35) *Quickly moving on, re-running the program, ignoring physical issue*
Accounting for Technical Issue (12) *Explicitly addressing the physical cause of a failed program*

Case 1: Resolving a programming bug without mechanical interference

Typically, when we think of debugging, we imagine programmers fixing a problem *in the program*. At times during coding lessons, children resolved programming bugs in this commonsense manner, without the materials interfering in debugging. We designed a task called *What Happened?* to explicitly teach debugging strategies for resolving common programming errors. The *What Happened?* task involved giving children buggy code that failed to get the robot to its goal and asking them to debug the program. In one such task, Lacey and Max worked together to diagnose and fix the broken code LEFT FORWARD FORWARD, where the bug was a wrong turn in the start position. The appropriate debugging solution was to swap the start code, replacing LEFT with RIGHT.

[a] Lacey: You have to turn him this way and get him to

[b] Max: No, no, no, the blue

[c] Lacey: That one? Oh, yeah!

[d] Max: We had to change it to blue

Figure 1. Lacey and Max debug a programming bug

Start position bugs involving rotations proved particularly challenging for children; many children applied strategies such as adding on to the end or removing the start code altogether to resolve this bug, resulting in multiple failed debugging attempts. After simulating how they wanted the robot to move, Lacey initially appeared to *re*apply the same wrong turn in their debugged program (Figure 1, a). Max quickly intervened, asserting that they needed the "blue" (i.e. the RIGHT) turn (b). Lacey clapped her hands excitedly to indicate agreement, and they compared their program with the buggy program to specify the location of the bug (c,d). With the robot turned off, Max and Lacey then demonstrated what their debugged code would make Botley do by simulating the movements. They were able to focus on the programming error, since no mechanical issues interfered in their debugging.

Case 2: Reorienting to a physical bug as a potential problem source

Programming bugs are a ubiquitous part of building algorithms, especially for novice programmers, who, in addition to learning a programming language, must also learn language-independent conventions for expressing meanings within a formal system of mechanistic rules (Pea, 1986). One thing all beginning programmers must determine is how much the computer "knows" and how explicit to make their commands in light of the built-in constraints. Tangible coding toys are built to make 90 degree turns, therefore establishing the correct starting orientation before initiating a program is paramount. Regardless of design, all tangible coding robots we use have a "face" that assists children in establishing robot starting positions. Still, forgetting to set the robot's orientation before running a program over multiple debugging attempts was a continuous source of physical bugs. We refer to these bugs as "initialization bugs"; however, rather than written code that would declare and clear variables and set initial states, initialization bugs take place *in the physical, tangible domain* where they represent failures to re-set the robot itself on the proper trajectory.

Figure 2. Jessica reorients the robot (left) and then reenacts this strategy (right). *Counter-clockwise from Jessica: Penelope, Paulo, Max, Lacey*

While reviewing Botley's movement-code correspondences during one lesson, the teacher Jessica used a just-in-time re-orientation to probe children's understanding of the critical concept of initializing the robot (Figure 2). The group was about to run a program LEFT FORWARD that was intended to land Botley on the blue tile. However, the robot was mis-oriented from a previous program; in the direction it was facing, LEFT FORWARD would have landed it *off* the tiles and on the carpet in front of Max (a frequent mishap that was a source of endless amusement for children). Just as Paulo pushed the button on the remote to run the program, Jessica realized that the robot needed to be re-oriented and swiftly rotated Botley 90 degrees to the right. After the program successfully reached the blue tile, she then paused to reenact her last-minute rotation, asking the children why they thought she had re-oriented it. Max suggested that Jessica was trying to "control" it (she was) and Lacey offered that it "didn't work" (it did). The children's reasoning about physical problems that require their own sort of debugging was still developing. It was, therefore, important that Jessica prompted them to examine the physical requirements of the programming environment. Doing so at a moment like this, when there was no concurrent problem in the program, supported them to develop repair strategies they would need when programming and physical bugs co-occurred.

Case 3: Reconciling concurrent programming and physical bugs

While the first two episodes show how young children address and resolve bugs, debugging was rarely this simple, and often involved a cascade of recurrent- and concurrent- bugs. Most coding lessons included multiple target programs, each of which required debugging over some number of attempts, which involved resolving both physical and programming bugs. When physical and programming bugs co-occurred, children and teachers needed to find both a debugging strategy that fixed the code *and* a repair strategy that mitigated physical bugs. More often than not, teachers intervened and interrupted physical bugs before they caused the whole program to miscarry, for example, when Jessica applied a just-in-time fix to a potential initialization problem. As children worked together to learn how to program *and* how to use the robots, bugs proliferated, compounding their problem-solving.

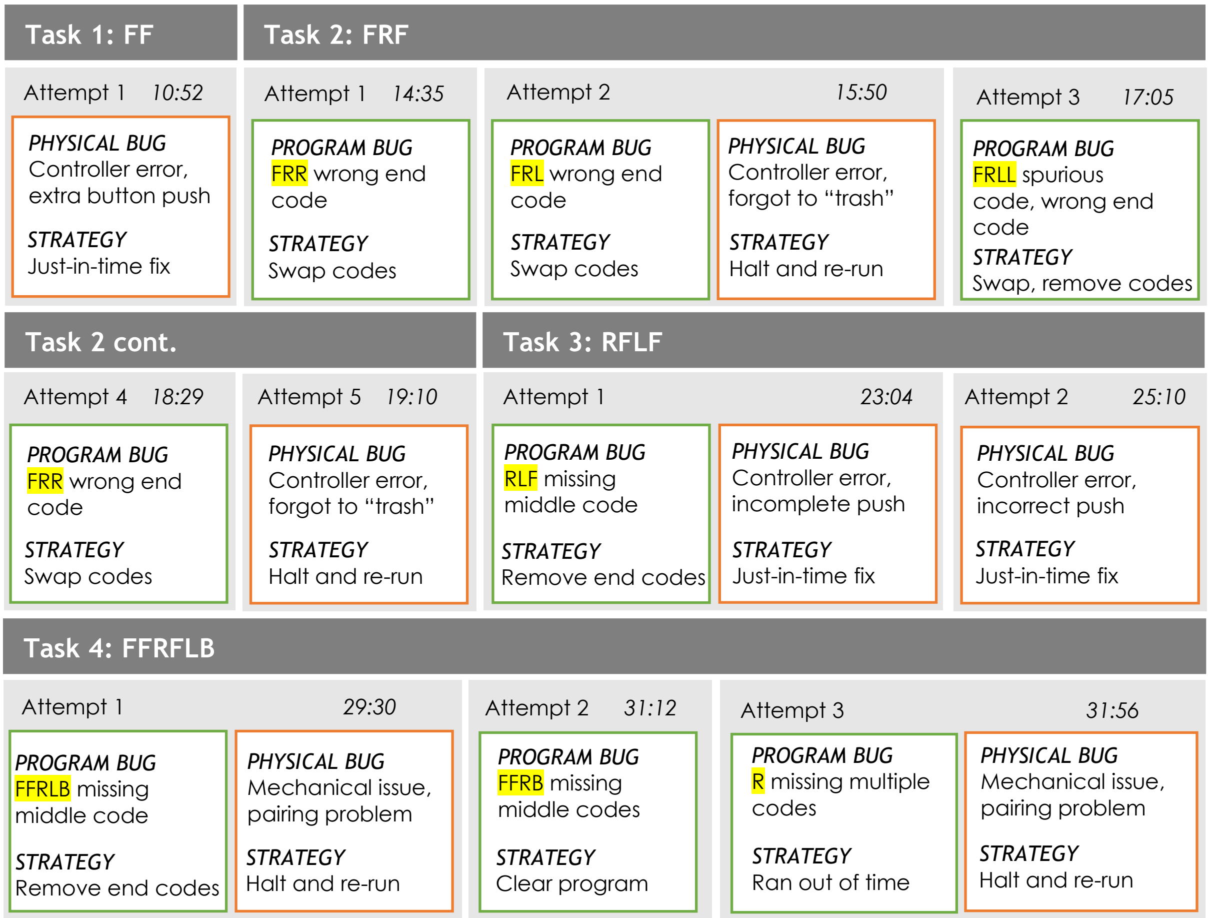

Figure 3. Outline of debugging during a 30-minute coding lesson.

Next, we sketch the anatomy of a coding lesson (comprised of a series of tasks, target programs, attempts, concurrent bugs, and debugging discussions) (Figure 3). We then zoom in on a single task in the lesson to show how the group organized their shared work and materials to handle programming and physical errors. This particular lesson involved an activity design called *Crack-the-code*, in which children attempted to program one Botley to run the hidden code of another Botley after they watched its movements. The children alternated between planning the program, sequencing the arrows, and pushing the commands on the remote control, sharing the materials and rotating roles between tasks. After solving a number of concurrent programming and physical bugs in the previous two tasks and cracking the code for the programs FORWARD FORWARD (FF) and FORWARD RIGHT FORWARD (FRF), the children attempted to crack a third target program: RIGHT FORWARD LEFT FORWARD (RFLF). After watching the first Botley run the program several times, Eli attempted to replicate it, instructing his programming assistant Stanley to sequence the codes RIGHT LEFT FORWARD (RLF).

At this point, they had produced a single programming bug; the program was missing a middle FORWARD code, for which the most efficient debugging strategy was to move the two end codes down and insert the missing code. However, before they ran the buggy program to test it, they first had to avoid potential user errors. After Joey reminded Christian to "trash out" the remote to delete the previous program, Christian began to enter the three codes into the remote, but Joey noticed that Christian pushed one of the buttons only half-way (the robot lights up when a full button push is registered). Joey stopped Christian inputting commands and instructed him to "push it harder." Joey called out the colors that corresponded with the arrows, and Stanley assisted Christian by pointing to the buttons (Figure 4, a). Joey's and Stanley's assistance with the physical material prevented user errors that would potentially have muddled Eli's programming bug.

After they ran this first buggy program and the robot failed to land where they intended it to, Stanley exclaimed excitedly that they get to do some "re-bugging" (b), coining a term that aptly describes children's recurrent attempts to debug with robot coding toys. When Joey asked Eli if there was anything he wanted to "fix" or "change," Eli was initially unsure. He began to demonstrate over the robot which way he wanted it to turn, referencing directions and colors of the tiles (c). As part of the process of learning to debug, children often described what they wanted the robot to do by referencing the physical grid space before blending these movements with the relatively unfamiliar and abstract domain of the program (Silvis et al., 2020). Eventually, Joey suggested that they remove the end codes and test each code one-by-one (d). This was a basic strategy teachers used with novice coders, who were more successful debugging programs when they could simply incrementally add onto the end of the sequence, fixing codes one at a time as necessary.

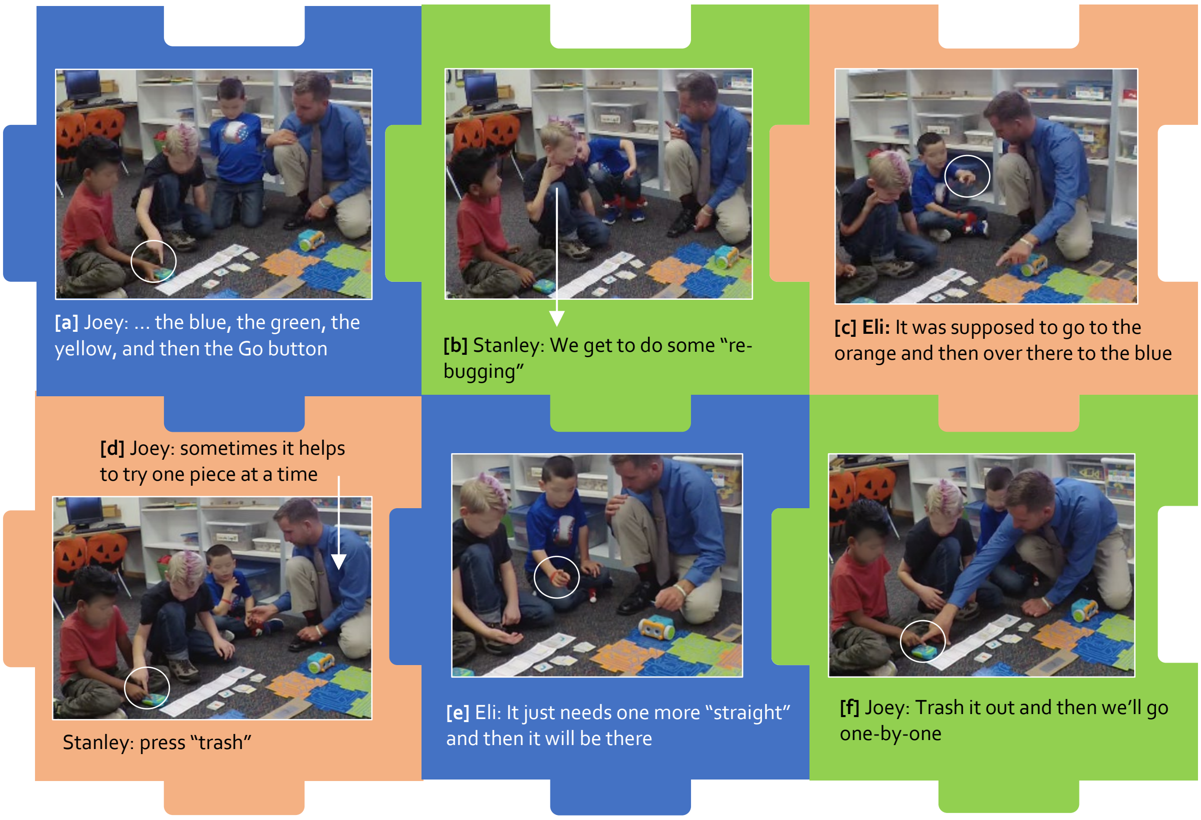

Figure 4. Debugging during Task 3

Following instruction from Stanley about trashing out the program in the remote control and pushing the Go button, Christian ran a single RIGHT command. Having isolated the initial movement, Eli then sequenced the remainder of the new program with Stanley's help (e). It was again time for Christian to program the codes into the remote control. Having observed multiple remote control-related user errors, the whole group was by then carefully monitoring Christian's operation of the remote. He successfully pushed the blue (RIGHT) and green (FORWARD) buttons, *but then mistakenly pushed another forward button* before the right turn button. Joey told him to press trash and start over, a just-in-time repair strategy in the physical domain that circumvented program failure. Joey pointed to the trash button and then told Christian to push the buttons "one-by-one" (f). Stanley pointed to each of the arrows in the program as they called out the arrow colors to Christian. In the course of the RFLF task, the children had applied both debugging strategies to the program and repair strategies to the physical materials. One-by-one coding and one-by-one button pushing were required to resolve errors in the program *and* prevent errors in the physical materials. We turn in the discussion to the ways in which tangible programming involves learning to debug both domains.

Discussion: Objects to debug with

In this paper, we presented the idea that tangible programming lends itself to forms of debugging at the level of the program and in the domain of the physical materials. Because coding robot toys are comprised of multiple, manipulable components, bugs occurring in the physical domain, such as forgetting to delete the previous program or pressing the wrong button on the remote control, can make it challenging for children to tease out errors in the program. Teachers' just-in-time strategies for addressing physical bugs- and for making technical requirements more transparent for children- may partly mitigate confusion; however, children must still grapple with the relationship between errors in their programs and errors due to the materials. As such, tangible toys can be thought of as "objects to debug with," which introduce novel orders of problems to solve. In a programming context where the success of a program hinges as much on accurately sequencing as it does on reliably inputting codes, operating materials and tangible programming go hand in hand.

Another characteristic of this particular computational environment that is consequential for coding involves the semantics of the coding language. The operative symbol system is a collection of color-coded arrows, a language that instantiates the meaning of directional commands in a symbolic form legible to preliterate children. However, Kindergarten children are also developing early spatial reasoning skills that implicate these same directional symbols; thus, learning the movement conventions of tangible toys (i.e. how the robots operate in 3D space) is entangled with learning the movement-symbol correspondence (i.e. how the symbols operate within a program) (Silvis et al., 2020). This complexity is compounded when the physical materials malfunction, or when there are user errors. The children in the cases we presented above are simultaneously learning *at least* the following concepts and conventions: (1) to perform mental rotation in 3D space (2) that the turn commands do not move the robot to another square, but merely rotate them on the same square (3) that the sequential actions of the robot depend on a precise sequence of codes and (4) how to input this same planned sequence of codes into the remote control.

Given the constraints built into the robots and this series of correspondences children are learning, concurrent physical and programming bugs require children to grapple with the larger programming environment or computational system. Whereas coding toys may appear straightforward and "user friendly" compared with screen-based or hybrid alternatives, tangible programming often involves solving both semantic (i.e. programming) and pragmatic (i.e. environmental) problems. Rather than a design flaw of tangible toys, we see this complexity as a resource for learning to debug, because it forces children to consider the broader relationship between all the components of the computational system: the codes; their meanings; their function (i.e. to give instructions to the robot); the robot and its movement constraints; coding robot accessories like the remote control (how does it "talk" to the robot, anyway?). Learning to coordinate these computational components to solve problems is a tall order in Kindergarten- especially when groups of children program collaboratively- but one that we see as productive for learning and consequential for their engagement with computing down the road.

Finally, while we focused in this analysis on the relationship between concurrent programming and physical bugs and the consequences of these co-occurring bug *types*, we also see a need for more study of the corresponding *strategies* students and teachers used to resolve bugs in both domains. Successfully resolving bugs requires an alignment between bug type and solution strategy. When children attempt to debug a programming bug in the middle of the program by adding onto or removing codes from the end, they fail to debug the program. Teaching children to apply particular debugging strategies to particular types of bugs is important across programming environments, no less in tangible programming (Klahr & Carver, 1988; McCauley et al., 2008). However, coding robot toys also require learning to apply a strategy to fixing the programming bug that teases out and takes into account the presence of concurrent physical bugs. This means placing pedagogical focus on the technical requirements/constraints of toys and teaching children not only how to fix problems with their programs but also how to diagnose and repair problems with operating the robots. Tangible programming environments expose how learning to debug does not simply follow from learning to program. We need to design for debugging (e.g. Fields et al., 2016), and treat tangible coding toys as objects to debug with.

Conclusion

The recognition that debugging is an important skill for programming has led to a number of studies. However, most of these studies focus on older students who are literate and interacting with computer screens. Very few studies focus on how young, preliterate children learn to debug. Integrating CS into early childhood requires a deeper understanding of the context and materials with which young children engage while learning to program. Preschool and kindergarten aged children often use tangible and hybrid coding toys that use directional arrows as a syntax. Programming these robot toys requires children to push buttons or manipulate tiles, often external to the toy. Thus, understanding how young children debug requires understanding the level of complexity the materials introduce and the nature of both the programming and physical bugs they encounter. Insofar as young children are learning how to operate these materials while they are learning to code, interactions with the toys are consequential for learning. More study is needed of the pedagogical approaches that support children to align their debugging strategies with the types of bugs they encounter. As learning designers, attending to tangible programming toys as objects to debug with provides insight into young children's thinking and supports them developing valued computational skills and knowledge.

Abstract: While science education has traditionally privileged detached and "settled" inquiry of natural phenomena (Bang & Marin, 2015), in this paper we discuss instances in which children leverage perspective-taking to explore the phenomenon of pollination through a more relational stance. We focus on two days of an eight-day mixed reality (MR) enhanced, embodied modeling curriculum where students play the roles of bees and flowers. We illustrate how the MR inquiry process supported students to take perspectives that they might not have otherwise. These different perspectives demonstrated a range of relationships to science and nature (e.g., friends, protectors, etc.). Our findings indicate that children disrupted traditional third-person views on scientific phenomena by taking the perspectives of and building empathy towards bees and flowers. Implications include the potential to further leverage perspective-taking and empathy-building towards desettling nature-culture relations (Bang et al., 2012) in future designs.

Keywords: perspective-taking, play, science education, mixed-reality, nature-culture relations

Major issues and significance

Science is a sense-making tool we use to examine and understand the world. Some definitions of science focus on the systematic organization of knowledge, while others define science in terms of the methods and practices used to produce knowledge such as observation, modeling, argumentation, and experimentation (NGSS Lead States, 2013; Ford & Forman, 2006). In most Western industrialized constructions of science, humankind is positioned apart from the object of study. We study the world, but we are not part of the world we are studying (Berkovich-Ohana et al., 2020). Our conceptions of science and objective truth lead us to take a spectator's position. However, this is not the only way to understand the world. Indigenous practices offer alternative epistemologies of science and the production of knowledge (e.g., Cajete, 1999; Bang & Medin, 2010; Bang & Marin, 2015) where humans attempt to better understand the world by positioning themselves as interconnected with the phenomena of interest.

Recent advances in digital technologies, such as mixed reality and augmented reality, are creating opportunities to learn science in new ways that invite students to study a phenomenon by becoming the phenomenon and taking a first-person perspective on the world rather than an observer's third-person perspective (Keifert & Stevens, 2018). One can study the orbits of planets and comets by becoming them (Lindgren & Johnson-Glenberg, 2013) or better understand pollination by becoming bees (Tu et al., 2019). To date, the majority of research in this emerging sub-field of the learning sciences has investigated how embodying the phenomenon creates new resources and metaphors for understanding the content (Enyedy et al., 2015; Lindgren & Johnson-Glenberg, 2013), but less attention has been paid to how perspective-taking may lead to more empathetic and less human-centric relationships to the content (for an example of a study that moves towards these design goals in technology-enhanced learning environments, see Lyons et al., 2013).

In this paper, we investigate how learning about pollination through the eyes of bees (and flowers) in a mixed-reality environment titled Science through Technology Enhanced Play (STEP) led students to think about the interdependence of bees and flowers from a first-person perspective and how that created space for alternative constructions of science and nature. We argue that the shift from third-person observer to first-person experiencer of natural phenomena not only supports scientific sense-making, but also emphasizes relationality and empathy with more-than-humans. Such relationality and empathy help to dismantle the nature-culture divide—the importance of which cannot be understated given the current moment of the Anthropocene (Guyotte, 2019).

Theoretical approach

The design of STEP is premised on the fact that socio-dramatic play is often a form of informal inquiry where one can explore a phenomenon by stepping into and playing a role. When people think of children's pretend play, they often think of the type of play chronicled by Vivian Paley (2004)—playing superheroes, school, or house—where children take on roles with power and authority that they do not have access to in their daily lives. Most of these contexts are familiar to children, but not fully understood by them. For example, when children play "house," they take on culturally meaningful roles such as mothers, fathers, and babies. They place these roles in a specific context often by saying, "*Let's pretend that* [you are the mommy and I am the baby and I am sick]." Notably, when the children begin the scene, they do not fully understand all of the dynamics at play, such as gender roles or the rules of parenting. It is through play that they attempt to make sense of what parents do and why. This is why play is a form of first-person inquiry: through play, children are able to inquire into an aspect of their lives they do not fully understand by inhabiting different perspectives than their own. STEP leverages play as inquiry to explore scientific phenomena.

Previous studies of STEP have explored the relationship between rules in play and embodied scientific modeling (DeLiema et al., 2019; Tu et al., 2019), and have demonstrated that embodied modeling in STEP supported learning gains in challenging complex systems concepts (Enyedy et al., 2015; Danish et al., 2018). In this paper, we are interested in the connection between emotion and cognition in play. Nicolopoulou (1993) argued that "play can mobilize emotions to achieve cognitive ends" (p. 16) and discussed this primarily in relation to how children come to understand their social worlds. We extend this idea to consider how emotions evoked by play in STEP supported students to develop understanding of and new ways of relating to the natural world.

Given our interest in students' conceptions of and relationality with nature, we found perspectives from environmental psychology and Indigenous scholars to be helpful for our analysis as well. With regard to the former, Schultz (2000) proposed a three-factor structure for environmental concerns: egoistic (motivated by rewards/harm to self), altruistic (motivated by rewards/harm to other people), and biospheric (motivated by rewards/harm to living things and the biosphere), with each factor linked to a person's notion of self as independent, interdependent with other people, or interdependent with all living things, respectively. He found that taking the perspective of animals being harmed led to increases in individuals' biospheric concern. With regard to the latter, Indigenous scholars critique traditional views of humans as independent and separate from nature. Bang and Marin (2015) argue that settled expectations of nature-culture relations, which position humans as distinct from the natural world and ignore non-humans' agency, dominate science education and restrict learning. They discuss how recognizing the presence of Indigenous ways of knowing and constructing non-humans as agentic enables "distinct and expanded forms of agency, perception, explanation, and ultimately meaning-making" (Bang & Marin, 2015, p. 541). Engaging students with heterogenous ontologies and epistemologies opens up new ways of understanding science and nature and has the potential to empower marginalized learners whose ways of knowing are typically repressed (Bang et al., 2012; Bang et al., 2017). Though the STEP curriculum was not intentionally designed to transform nature-culture relations, reviewing our data led us to identify vignettes where young children took varied perspectives, sometimes seeing humans as separate and other times blurring the nature-culture boundary, as they made sense of pollination. A close look at students' negotiation of different perspectives in their play yields insight into ways of understanding natural-cultural systems and nature-culture relations that are not often seen in traditional science classrooms.

Methodological approach

This study focuses on two episodes from an eight-day curriculum on bees and pollination in the STEP environment, a mixed-reality learning environment designed to leverage play and embodiment as resources in scientific modeling and inquiry. The STEP environment uses motion sensors to track students as they move about the space and embody honeybees. A virtual simulation is superimposed over the live video feed of the classroom and shows each student's digital bee avatar as it interacts with a virtual beehive and flower patch on a projector screen (see Figure 1).

Figure 1. Students move around the STEP space as bees while their bee avatars move between flowers and their hive on the projector screen at the front of the room.

The overall STEP project took place in two schools, one in Indiana and one in California, in a total of six classrooms. This was the second iteration of STEP in both schools and was the second time the teachers had implemented these lessons in their classrooms (although new features of the environment led to some lesson revision). The 25 participants in this analysis were from one first- and second-grade mixed-age Spanish-English bilingual classroom at a progressive elementary school in California. Although the participants were multilingual and the classroom was a dual immersion classroom, according to the teachers' preference, the STEP activities for this classroom were conducted in English. Data sources for this analysis included the video recordings from Day 6 and Day 8 of the intervention. The focal class engaged in the STEP environment in two separate groups and we reviewed video of both groups. We found similar themes across the class as a whole, and in this study, we present an analysis of Day 6 video with one half of the class and an analysis of Day 8 video with the other half. This class was initially selected to pursue a research question concerning how non-linguistic resources were employed and valued in a bilingual setting. The analysis here emerged from our observations while pursuing that initial research question.

Prior to Day 6, students engaged in approximately four hours of sociodramatic play from the perspective of bees, exploring different strategies for collecting nectar from flowers. On Day 6, the focus shifted to pollination. Students explored the difference between nectar and pollen through the “Bridge to Pollination” game. In this game, some students sat in the STEP space and acted as red, blue, or yellow flowers who gave pollen (red, blue, or yellow stickers) to their classmates, who acted as bees foraging for nectar. Within a 1–2 minute time limit, bees were tasked with visiting their flower friends to collect nectar, while flowers distributed pollen to each bee who visited them. While students engaged in the game, the projector screen showed the bees moving around the flower patch, leaving pollen trails behind them as they moved from flower to flower. After the time ran out, the researcher advanced time forward in the projected environment to show which flowers grew or died. Flowers that were pollinated (i.e., flowers that were visited by bees who had already visited a flower of the same color) grew and were replaced by a cluster of flowers on the screen, while flowers that were not pollinated died and were replaced by a wilted flower on the screen. Students debriefed the embodied activity with the goal of understanding that a flower can only be pollinated and grow if there are other flowers like it, and if bees distribute pollen from one flower to another flower of the same kind. On Day 8, the last lesson of the curriculum, students engaged in more embodied activities on pollination and discussed the interdependence between bees and flowers.

The research team watched video recordings of Days 6 and 8, time indexed the two lessons, and reviewed the data to identify shorter clips that highlighted students' perspective-taking. The research team then watched these selected interactions repeatedly, both individually and collectively, looking closely at the micro-interactions to iteratively develop and refine our conjectures about how perspective taking was playing out in student talk and actions (Erickson, 2006). These clips were also transcribed, and the transcriptions were edited by members of the research team to include important paralinguistic behavior (e.g., facial expressions, pointing, laughter; Jefferson, 2004). At this point in our theory building, we have not returned to the larger corpus to see how our findings generalize to other classrooms. Instead, consistent with the early phases of grounded theory (Charmaz, 2006), we have focused on making sense of the student experience by examining student arguments and explanations on Day 8 of the unit for which perspective it centered. While our project design did not explicitly include Indigenous epistemologies, during our analysis we found this line of research important and helpful to consider as we investigated the following research question: How did learning about pollination through the first-person perspectives of bees and flowers contribute to students’ empathy for and understanding of the interdependence of bees and flowers?

Major findings

We found several episodes where the technology of STEP encouraged students to take a first-person perspective as bee and flower agents acting out the phenomenon of pollination. This perspective-taking led students to pursue a different line of inquiry than if they were limited to the outsider human perspective traditionally taken in science classrooms. By analyzing the moments when students expressed less human-centric perspectives, we found evidence of more holistic and empathetic stances towards nature.

Episode 1: Developing empathy for nature through the blurring of nature’s systems and interpersonal relationships during play

The first episode occurred during the “Bridge to Pollination” activity on Day 6. As noted above, this was the first lesson in which students acted as flowers. In this instance, two students embodied blue flowers, two embodied yellow flowers, and one embodied a red flower, although up until this day the color of the flowers had never mattered because a flower’s nectar quality and quantity had no relationship to color. When the game concluded, the bees returned to the hive for winter, and the researcher asked the flowers to make a prediction about their prospects. If they thought they would reproduce and survive the following spring, they were told to stand; if they thought they would die, they were told to sit down. Andrea, the red flower, was the only student to stand, exclaiming, "I'm full of nectar!" (Figure 2). In former lessons, as a bee, being full of nectar would have signaled survival, so it seems Andrea may be conflating that experience with her role as a flower, for which being full of nectar actually means she was visited less often by bees.

Figure 2. Andrea predicted she would grow while the other flowers remained on the ground (left). When time was advanced, the projector screen showed that the red flower died while the blue and yellow flowers grew (middle), and the students embodied this as flowers (right).

The researcher then advanced time forward and the red flower on the screen died while the yellow and blue flowers turned into bunches of flowers (see Figure 2). In a moment of recognition, Andrea groaned and fell to the ground in a dramatic play-death, her arms and legs spread out like a snow-angel. Zara, who had predicted she herself would die in a similarly comically splatted death pose, with arms to the sides and one knee turned inward, suddenly registered that her flower on the screen had in fact grown. She jumped up exclaiming, "Oh I actually grew!" and the other flowers followed suit with cheers of "I grew!" One student, Maria, was so excited she began jumping and dancing in circles. Meanwhile, Andrea, still splayed on the ground, stated matter-of-factly, "I'm dead," and two students at the back of the room called out, "Andrea died."

At this moment, amidst the commotion of Maria dancing, laughter, talk at the back of the room, and the teacher asking, "What do you notice about the flowers that grew and the one that didn't?" Dylan, a student who had been clustered at the back of the room, launched himself into the space, chest first, exclaiming, "Oh!" He ran to Andrea and gingerly placed a sticker on her outstretched arm, as she laugh-lamented, "I'm de-he-head," then ran back to his teacher. Dylan turned to point toward Andrea and loudly announced, "Everybody give pollen to Andrea!" The teacher, seemingly precluding a mad rush to Andrea, said, "Well, let's talk about why that happened. Why do you think that happens? All the flowers grew except for Andrea." Dylan looked up at the screen for a few moments, taking in the imagery. Meanwhile, a researcher at the front of the room approached Andrea to sympathize with her, announcing playfully, "You're dead! I'm sorry." Dylan's gaze shifted from the screen, to the researcher, and then he turned to his teacher to explain, "Cause she didn't have any flowe= she didn't have any pollen left." The teacher began to question Dylan's reasoning, noting the pollen trails that led to and from the red flower on the projection screen, but their conversation was cut short as the teacher had to quell the rising volume of multiple students talking at once.

There are multiple noteworthy aspects of this episode. First, students' embodied experiences of playing flowers reveal an emotional connection to the phenomenon of pollination. We see this impact in Andrea's mournful groan and withering to the floor as she realized her flower had died, and in the other students' exuberant jumps up to standing as they realized their flowers had grown. One could dismiss this affective engagement as immaterial to what the students were learning but we argue below that it plays an important role in fostering students' empathy for more-than-humans and supports their sense-making. As Nicolopoulou (1993) describes, "play is a form of symbolic action, with a significant ritual element, which may thus have a powerful emotional impact on participants" (p. 16).

Second, in both their language and actions, students seem to blur the nature-culture divide that dominates most science learning environments (Bang & Marin, 2015). When students shared what they noticed, they did not say, "Andrea's flower died," but rather, "Andrea died." While students certainly knew that Andrea was playing a flower and had not herself died, their language blurred the barrier between humans and nature. This blurring seems to have invited more expansive forms of scientific sense-making (Bang et al., 2017) as students' emotional connection to their friend became a resource and motivation for understanding a natural system. Specifically, Dylan's immediate impulse to help Andrea by giving her pollen and urging his peers to do the same suggests that his orientation toward his friends had, at least for the moment, been extended to nature. Relating to Andrea, the flower, as a friend that should be helped, Dylan's empathy for people was extended to nature and this deepened his understanding of flowers' dependence on bees. The blurring of the nature-culture divide that is evident in Dylan's actions suggests that engaging in science inquiry through play created space to make sense of the natural system of bees and flowers through a desettled lens in which more-than-humans are agentic (Bang & Marin, 2015). Furthermore, drawing from Schultz's (2000) finding that taking the perspective of harmed animals increased biospheric concerns, we see Dylan's empathy, which was spurred by assuming bee and flower perspectives, as a possible impetus for increased biospheric concern. We discuss relationships between perspective-taking and environmental concern further in relation to Episode 2 below.

Episode 2: Understanding interdependence by expanding sense-making resources to include perspective-taking

On Day 8, a different group of students from the same class continued to explore pollination in the STEP space. This time, rather than sprouting more flowers, the flowers turned into fruits, vegetables, or cotton when they were pollinated. After the embodied activity, students sat down to debrief when a researcher posed the question: "Do you think pollen or nectar is more important?" Initially, there was an emphatic chorus of "Nectar!" with one girl noting, "You can make honey," and a lone quiet, "I think pollen." After a student named Oscar defiantly exclaimed that he'd already asked this question, the researcher reiterated it, asking, "What did you guys decide on?" This time, a few students tentatively whispered, "Nectar," followed by more vocal responses of "Nectar," a sole assertive, "Pollen," from a student named Ramona, and an "I don't know" from Oscar. Ramona was then the only student to raise her hand when the teacher asked who thought pollen is more important. The following discussion transpired when the teacher asked Ramona to explain her thinking:

Ramona: When the pollen goes to the other flower, um, it pollinates.
Teacher: It pollinates. So your=
Oscar: Yeah but if bees don't have nectar then [the bees won't survive.].
Isabelle: [We don't have honey.] And we don't have honey.
Oscar: But there is also other pollinators…
Matthew: But it's good for the[… plants.]
Oscar: [but it's also,] they also need nectar.
Teacher: So what do you think Matthew? Do you, do you think it's nectar or=
Matthew: It's kind of both cause=
Teacher: =pollen?
Oscar: It's like more or less, they're both [pretty important. They're both pretty important cause for the bees to survive=]
Matthew: [Yeah, cause it's better… I was gonna say it's better for the bees.]
Teacher: Hold on one person at a time. Go ahead Matthew.
Matthew: It's also good for the bees and for the plants, and the flowers right.
Oscar: (quietly) The plants are giving the bees something and the bees are giving the plants something.
Teacher: Ah, say that nice and loud.
Oscar: The plants are giving the bees something and the bees are giving the plants something.
Matthew: That's what I was saying.
Teacher: That's what you were saying.
Oscar: So they're both really important, pollen and nectar.
Teacher: So you think they're both just as important?
Oscar: Yeah because, first of all, if they don't have, if flowers didn't have pollen they would never be able to fertilize the seeds and they wouldn't

```
                    grow into plants. And if bees didn't have nectar
                    then they would all die. And other pollinators
                    need nectar.
Teacher:            Hmmm.
Isabelle:           So it's technically both and balanced because we can't
                    choose one over the other. Because if we get rid of
                    one, something won't survive, and if we get rid of
                    the other one something won't survive. So we need them
                    both to survive.
```

Considering this discussion in the context of the eight-day curriculum, during which students primarily took the perspective of bees, reveals much about students' responses to the pollen versus nectar question. From the bee perspective that they had been taking, it makes sense that most students privileged nectar at the beginning of the discussion; as bees, students experienced how critical it was to collect enough nectar to survive through the winter. This makes Ramona's contrasting insistence that pollen is more important all the more significant. Ramona, having played a bee for the majority of the unit, chose the more altruistic option of pollen—the resource that is critical to flowers rather than bees. We should note that during one round of the "Bridge to Pollination" game on Day 6, Ramona embodied a flower that did not get pollinated and died, so it is possible that she is recalling the perspective of being a flower in her "pollen" response. However, given the predominance of her experiences as a bee, and the fact that she witnessed the demise of her friends as flowers in multiple other rounds of the game on Day 6, it seems plausible that she chose pollen out of altruism, perhaps spurred by an empathy similar to Dylan's in Episode 1. Either way, her thinking seems to be biospheric (Schultz, 2000), as she expressed the importance of pollen for the flower's sake. Moreover, it makes us wonder if the collective perspective-taking in the "Bridge to Pollination" game, and in particular the opportunity to interact with friends in more-than-human roles, may be an especially potent recipe for developing empathy and biospheric concern. In other words, witnessing friends (in the role of more-than-humans) in trouble may inspire empathy and biospheric concern in similar ways to Schultz's (2000) finding that taking the perspective of animals being harmed increased biospheric concern. After all, our desire to help our friends is sometimes even stronger than our desire to help ourselves.

Oscar's varied contributions to the discussion further reveal the nuance, as well as the fluidity of students' ideas. Reading Oscar's comments through the lens of a more expansive set of science sense-making practices (Bang et al., 2017), which include the positioning of more-than-humans as agentic (Bang & Marin, 2015), helps us to understand the trajectory of his ideas from uncertainty, to nectar being more important, to both pollen and nectar being important. Oscar's initial leaning toward nectar being more important reflects an affinity for the bee's perspective. Furthermore, his comment, "But there is also other pollinators…" (line 8) seemed to abdicate the responsibility of the bees to pollinate flowers. His later reflection, "The plants are giving the bees something and the bees are giving the plants something" (lines 29–30), gave agency to both bees and flowers. Here, he described their relationship in reciprocal terms reminiscent of kids' lunch-time trades in the cafeteria ("I'll give you a cookie if you give me some chips"). This led to his recognition that "they're both really important, pollen and nectar" (lines 33–34), and his final explanation (lines 36–41), which is more detached and "scientific" and focuses on survival rather than a reciprocal relationship. Therefore, it seems that taking the perspective of agentic bees and flowers mediated his sense-making about the interdependence of bees and flowers. He even expanded beyond bee-flower interdependence to acknowledge how other organisms depend on the survival of flowers, noting, "And other pollinators need nectar" (lines 40–41). Oscar was able to generate this expanded and sophisticated conclusion by drawing on his own prior knowledge, inquiry experiences in the STEP space, and importantly, a more expansive set of sense-making practices (Bang et al., 2017) that blurred the nature-culture boundary. It is also notable that throughout Oscar's perspective-taking and sense-making, he, like Ramona, seemed to evaluate the importance of pollen and nectar from a biospheric stance (Schultz, 2000), placing value on the mutual survival of bees and flowers.

On the other hand, Isabelle engaged in the discussion from a human-centric stance. Her interjection of, "And we don't have honey" (line 7) in tandem with her conclusion, "So we need them both to survive," (lines 46–47), contrasts with the biospheric perspectives shared by other students, attributing value from an egoistic perspective (Schultz, 2000) of resource extraction. This egoistic perspective was echoed by several other students as the conversation continued. They named several products that depend on pollination, for example strawberries dipped in chocolate and cotton clothing. One student summarized her classmates' ideas stating, "I think it's an important thing that we have bees because they need to pollinate everything we own and a lot of things we care about." These comments are unsurprising given that the design of the STEP environment in this lesson intentionally focused students on the pollination of familiar agricultural crops on which humans depend.

Nonetheless, their reflection of settled expectations of nature-culture relations (Bang et al., 2012) presents a striking contrast to the blurred nature-culture boundary evident in Episode 1 and in some of Oscar's sense-making.

It is important to note that students' discussion of humans' relationship to bees and flowers was not solely from an extractive, egoistic stance. In addition to exploring how humans depend on pollination for everyday products, they discussed how humans sometimes harm bees, but ought to protect them. For example, they shared personal stories of witnessing pesticides kill bees and other animals, as well as suggestions that people ought to plant more flowers and not pick plants they find in order to help bees. Through this discussion, students acknowledged how humans are part of the natural system, both dependent on and having the potential to either harm or protect bees and flowers. Ramona summed this up, reflecting, "Basically we depend on bees to give us life and they depend on us to help them." This synthesis reflects a notion of self as interdependent with all living things, and thus suggests biospheric concern (Schultz, 2000). That said, it falls short of the desettled nature-culture relations that Bang et al. (2012) discuss—Ramona and many of her classmates conveyed a view of humans as separate and having power over nature's well-being, even as they expressed the need to protect bees.

Conclusions and implications

In this paper we have discussed how students engaged in play and perspective-taking to understand the phenomenon of pollination in ways that enabled more expansive sense-making opportunities (Bang et al., 2017) and disrupted normative nature-culture relations (Bang & Marin, 2015; Bang et al., 2012). In Episode 1, Andrea enacted a full-bodied emotional death as she played a flower, and this spurred Dylan's empathetic response of running to give Andrea/the flower the sticker/pollen he thought would save her. We argue that taking the perspectives of flowers and bees blurred the nature-culture boundary in this moment as empathy often reserved for other people was extended to the more-than-human world. In Episode 2, students fluidly leveraged different perspectives (bee, flower, human) as they debated whether nectar or pollen is more important, and in doing so revealed biospheric concern (Schultz, 2000) for bees and flowers. This discussion organically led into a conversation about humans' roles in the bee-flower system. Although students' discussion of humans centered around humans as extractors/protectors, thus somewhat perpetuating human-centric ways of thinking, we still believe that recognizing the interdependence of humans and nature was an important step towards desettling nature-culture relations.

It is important to note again that the STEP environment was not intentionally designed to explore or desettle nature-culture relations. Indeed, we recognize the irony of discussing an indoor technology-enhanced environment's potential to bring people closer to nature. Nonetheless, noticing the ways students expressed empathy for their friends as flowers, the fluidity of students' perspectives during the discussion of interdependence, and the spontaneous sharing about humans' roles in the system led the research team to consider STEP's potential to engage in this critical work. In future research and designs, we hope to probe these issues more deeply to realize this potential. Additionally, an important question lingers about the transferability of students' environmental concern and understanding of interdependence to other contexts. With regard to the transferability of environmental concern, Sevillano et al. (2007) found that taking the perspective of a particular animal being harmed led to biospheric concern for living things more broadly, and while this is promising, a need for further research remains. Future design implications include pairing experiences in the STEP environment with outdoor experiences, focusing on other natural systems, explicitly privileging heterogeneous ontologies and epistemologies, and intentionally using perspective-taking as a tool for building empathy with more-than-humans. In the midst of climate change, a perennial ethos of resource extraction, and the persistent separation of people from nature, efforts to repair and desettle nature-culture relations are paramount.

On the Impact of Differing Content Progressions in Genetics on Modeling Practices

Veronica L. Cavera, Ravit Golan Duncan,
Veronica.Cavera@Rutgers.edu, Ravit.Duncan@gse.rutgers.edu
Rutgers University

Abstract: Learning progressions present hypothetical pathways for learning concepts. Some progressions focus on instructional order while others focus on content. One of the open questions in the field attends to the interaction of content and practice. We investigated this interaction in genetics by: (1) comparing the order in which students access core genetics concepts, and (2) comparing the order of progressions in concert with model practices. We discuss data from model construction tasks in a modeling-based unit in genetics. In this instruction, 11^{th} grade students (n = 271) were provided five weeks of molecular genetics (n = 127) or classical genetics (n = 144), provided an assessment, which included the model construction task, and then moved to the alternate task. We present data from each of the modeling tasks. While students leveraged roughly the same amount of evidence in both conditions, *how* students used evidence differed in the two instructional conditions.

Background

Learning progressions (LPs) can help capture how students conceptualize their understanding of a practice or content. These establish what students are expected to learn in hypothetical paths as they develop increasingly sophisticated ways of reasoning in a domain over extended periods of time (e.g., Alonzo & Gotwals, 2012; Corcoran, Mosher, & Rogat, 2009; Duncan, Rogat, & Yarden, 2009). LPs are grounded in research on how students actually come to understand core ideas in the domain (rather than simple analyses of normative knowledge in the domain). Most LPs focus on the developmental understanding of either a practice or a set of core ideas. Fewer LPs systematically address the development of understandings and competencies in both of these dimensions and how they influence each other.

In order to explore the intersection of content and practice, it is necessary to consider whether different content LPs result in different understanding of the practice. In science, LPs strive to combine content and practice. There are a few key examples that demonstrate this integration (see, e.g., Songer, Kelcey, & Gotwals, 2009). However, the nature of this relationship is not always clear. Currently, how practice and content are married to each other depends on the intuitions of the researchers, as there is less work specifically evaluating the relationship between practice and content. In order to extend this work, we investigated this issue through the content lens of genetics. In this study, we investigated how two alternative progressions, which addressed the same core ideas, interfaced with modeling practice when the curriculum used to teach genetics ideas was model-based instruction. We bridge this gap in two ways: we (a) examine models constructed to explain genetic phenomena, and (b) examine how competing learning progressions impacts evidence usage, coherence, and overall model complexity.

Theoretical framework

Within the content realm of genetics there are multiple LPs that result in learning the core topics. These LPs differ in the assumptions about the sequence and levels through which these ideas develop. Stewart et al. (2005) identified three major models of genetics to compose genetics literacy. These include: (a) *the inheritance model*, which describes the pattern of inheritance between parents and offspring, (b) *the meiotic model* which describes the mechanism by which genes move from parents to offspring through sperm and egg (gametes), and (c) *the molecular model* which describes how genes are translated into protein which bring about physical traits. Stewart et al. (2005) argued that genetic literacy entails understanding and connecting all three of these major models. While students may be able to understand and articulate an aspect of each of these genetics models individually, they tend to have the greatest difficulty describing the mechanisms that underly each model, as well as connecting each model to one another (e.g., Duncan, Choi, Castro-Faix, Cavera, 2017; van Mil, Boerwinkel, & Waarlo, 2013).

One of the open questions in genetics instruction is related to the order of instruction—essentially what model should be taught first, to facilitate genetics understanding. Two separate research groups have independently worked with the Stewart et al. (2005) genetics literacy model to develop LPs that differ in their assumptions about the sequence and levels through which these ideas develop (Duncan, Rogat, & Yarden, 2009; Roseman, Caldwell, Gogos, & Kurth, 2006). Roseman et al. (2006) argue that the central concepts of genes, chromosomes, and alleles are abstract concepts and can be better conceptualized once students understand the structure and function of concepts like DNA and proteins. Understanding the *mechanism* at the cellular and molecular level by which genes bring about observable traits can serve as a way to support student understanding of the relationship between genes and traits across multiple generations. This, therefore, supports the connection between the genetic literacy model proposed by Stewart et al. (2005). Comparatively, Duncan et al., (2009) progression proposes that genetics concepts should be introduced in tandem and that a parallel learning model would facilitate better understanding. We note that the discrepancy in these suggested LPs comes, in part, from the current gaps in the research, especially in attending to student understanding of molecular genetics concepts.

The genetics LP used as the theoretical and analytic framework for this study is the Duncan et al., progression (2009). This framework combines the meiotic and inheritance model to comprise the Classical genetics model. The LP comprises eight primary ideas that map onto the Classical and molecular models. For example, the molecular model included that genes are instructions for making proteins while the Classical model included the idea that egg and sperm cells have half the genetic information, and that there are predictable patterns between an individual's genes and their traits. While both LPs make a fair argument for why their progression would better support content understanding, it is not obvious which content LP is best for supporting modeling. If traits and patterns of inheritance are somewhat familiar, perhaps it will be easier to model them as a starting point for students. Alternatively, understanding the molecular basis of genetics can help students understand inheritance patterns. LPs on modeling have provided valuable insight about student performance in terms of how models are constructed, revised, and evaluated (e.g., Passmore & Svoboda, 2012). Whether students discuss communicative or epistemic features of how models communicate (e.g., details, visuals), or epistemic standards are important to understand what students value within their models. What students value when creating models within genetics has been explored (e.g., Puig, Ageitos, & Jiménez-Aleixandre, 2017). However, there is less work on how it ties into the progression of understanding genetics content as it interfaces with modeling practice. Therefore, our research questions are: (1) does the order of instruction of learning Classical then molecular or molecular then Classical genetics influence model construction? (2) what kind of models do students construct during two parallel modeling tasks?

Methodology

Study context

The present study was conducted for ten weeks with five biology teachers and their 11^{th} grade students (n = 271) in a suburban high school in the North Eastern United States. The school was relatively diverse and 34% of students were eligible for free or reduced lunch. The school consisted of 47% African American, 22% Caucasian, 19% Hispanic, and 11% Asian students. In this district, students learn physics in 9^{th} grade, chemistry in 10^{th} grade, and biology in 11^{th} grade. Students took part in a modeling-based curricular unit in genetics (~10 weeks of instruction) that engaged students in the construction, evaluation, and revision of models of genetic phenomena. Students were assigned to a condition based on their prior scores in chemistry classes provided by the teachers in the study. Class conditions were counterbalanced within teachers.

Curricular Design and implementation

Students were engaged in five weeks of molecular-focused lessons that included topics about the central dogma of DNA and the role of proteins. The other five weeks of instruction covered concepts related to patterns of inheritance. Students were given both sets of instruction, half of the students (n =144) were given the *Classical* unit first (*Classical-first*) while the other half were given the molecular unit first (*Molecular-first*, n = 127). Both instructional learning modules included multiple modeling opportunities. For example, a Molecular-first student would complete five weeks of molecular instruction, then would complete five weeks of classical instruction while a Classical-first student would complete five weeks of classical instruction and then five weeks of molecular instruction (see Figure 1).

Prior to and after instruction students were given *content tests*. These were ordered multiple-choice (OMC) tests that assessed student understanding of core topics in genetics (Duncan, Castro-Faix, & Choi, 2016). Students were also given pre- and post-domain-general *modeling assessments* to assess their modeling practices (Cavera, Duncan, Chinn, Castro-Faix, 2018; Cavera, El-Moslimany, Duncan, Chinn, 2020). Students constructed and revised a model, and wrote an evidence-based argument with respect to a non-genetics topic that differed at the beginning and end of the study and were randomly assigned by condition. At the close of each curricular unit students were given a *content modeling assessment* which is the focus of this analysis. We report data from students who completed all of the modeling assessments and content tests (n = 271).

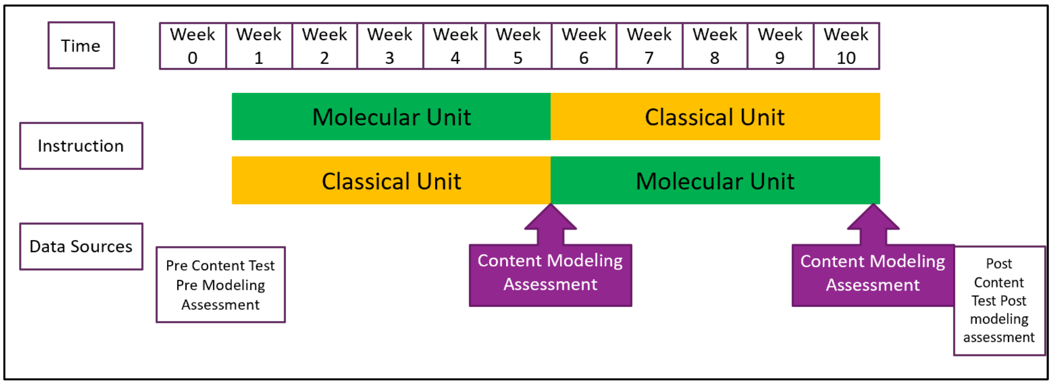

Figure 1. Instructional Order

Instrument design and data collection

The content modeling assessments were similar in structure and design, included two parts, and took sixty minutes to complete. Both assessments followed the same stylistic format in that the first part of the assessment tasked students with developing an evidence-based model of a phenomenon. Students were provided with three evidence pieces. In the Molecular Modeling Assessment (*MMA*) students were asked to develop a model that explained the biological mechanism underlying a hypothetical skin disorder (*DEB*) in which individuals had gaps between their dermis and epidermis skin layers resulting in painful blisters. The evidence provided to students included the identification of a genetic mutation as the cause of the disorder that may impact a protein (evidence 1), a description of the symptoms as gaps between the skin layers (evidence 2), and a picture of the layers of skin in normal skin (evidence 3) (Figure 2). Students were expected to construct a model to identify and predict if a genetic mutation was involved.

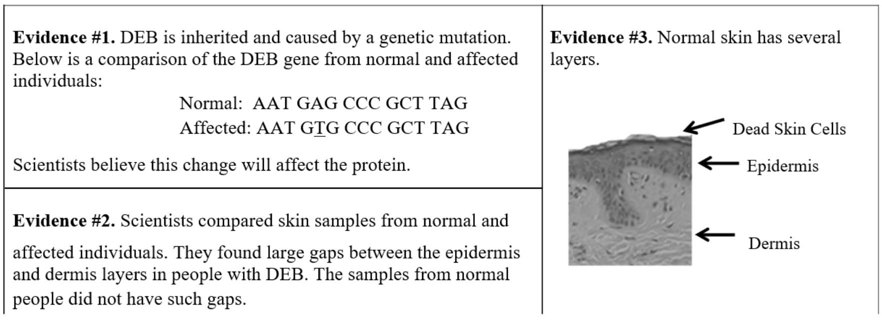

Figure 2. Evidence provided in the Molecular Modeling Assessment (MMA)

The Classical Modeling Assessment (*CMA*) tasked students with developing an explanatory model for the inheritance pattern that caused an irregular heartbeat (*FHD*). They were provided three evidences (Figure 3). These again included a description of the symptoms (evidence 1), a pedigree or family tree (evidence 2), and a ratio of healthy, affected, and offspring who died before birth (evidence 3). In both cases, the evidences were designed to provide clues about the underlying mechanism but not give away the actual mechanism itself.

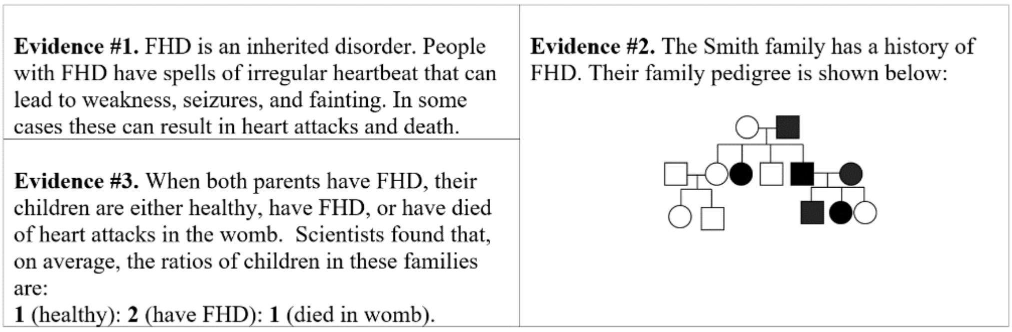

Figure 3. Evidence provided in the Classical Modeling Assessment (*CMA*)

Coding and analysis

Models from the content model assessments were coded along two major dimensions: evidence usage and a propositional analysis of domain knowledge (Duncan, Choi, Castro-Faix, Cavera, 2017). Evidence usage was counted in each model. While students were provided with three evidence pieces for the model construction task, we noted that students focused on specific aspects or parts of each evidence. For example, in the *CMA*, evidence 2 provided students with a family tree (pedigree) (see Figure 2). Students focused on the third *generation* of the tree where they explored the combination of affected and unaffected children; some focused on the disorder's appearance in each generation, while some students combined these ideas. Students who focused on the *children* in the third generation of the pedigree often discussed what the children's alleles must be so that they did not present the disease. For example, students could state that, *if the genotype of the child is* $F^H F^H$ *they will be healthy,* focusing on the genes of the possible children. Students who discussed the *generations* focused on the disease over generations in the family, for example, *FHD is inherited from Parent to Offspring…someone in each generation has it.* Some students *combined* these ideas discussing the *pedigree as a whole*. In this case students could describe the previous concepts, *FHD is passed down through your genes* (generational)…*if you look at the second family generation it shows parents who both have it. It shows 3 kids but 2 have FHD the 3rd does not* (children). In the *MMA*, evidence 1 (see Figure 3) described a mutation in a gene which may impact a protein. Some students focused on the *genetic* portion of the evidence, *the gene is mutated* and describing how that would impact the skin layers or drawing skin layers. Others focused on the possibility of the *protein* change, stating *People with DEB are missing a certain protein which in turn causes them to not produce enough Epidermis, causing large gaps.* Finally, other students used the evidence as a whole, *there was a genetic mutation with the gene, the protein was not able to be made. The missing protein caused there to be missing aspects of the skin since the skin is missing sections.* We captured how students discussed each of these mechanisms within student models.

Three independent coders coded 34% of the *CMA* data and 31% of the *MMA* data. Interrater reliability was 89% and 91%, *CMA*, *MMA*, respectively.

Results

We begin our analyses by comparing average evidence use by assessment and implementation order (Table 1). In the pre-modeling and post-modeling domain-general assessments there was little difference in which evidence students used or how the evidence was used to describe the phenomenon under investigation. In the *CMA*, students on average incorporated the same evidence the same number of times regardless of instructional order. However, we noted differences in *how* students used these evidences in their models and to what effect. Students who used evidence 2 (the family tree) or evidence 1 exclusively, developed largely phenomelogical models. This means they transcribed the symptoms (describing evidence 1), or focused on a largely phenomelogical aspect of the evidence or the generational aspect of the evidence. Students who combined evidence 2 with evidence 3 (23% *Classical-first*, 43% *Molecular-first*) were 1.7% more likely to develop a biologically plausible model. This indicates that students in the *Molecular-first* condition, while not leveraging more evidence than their *Classical-first* peers, used the provided evidence in ways that were more productive.

Table 1. Evidence use in both conditions during the modeling assessments

		Classical-first	Molecular-first
Pre-modeling assessment*	Average number of evidences	1	1
Classical-Modeling Assessment (*CMA*)	Average number of evidences	1.5	1.5
	Most frequently used evidences	E2(generations) and/or E3	E2(generations) and/or E3
Molecular Modeling Assessment (*MMA*)	Average number of evidences	2	3
	Most often used evidence	E2/and or E3	E1(central dogma) and/or E2
Post-modeling assessment*	Average number of evidences	1.5	1.5

*Pre/post modeling tests were randomly assigned by condition and class assignment.

In the *MMA*, *Classical-first* students on average used two evidences pieces while *Molecular-first* students used, on average, three evidences. We also note differences in *how* students leveraged these evidences and which evidences they used. First, students in the *Classical-first* condition tended to use evidence 2 or evidence 3 alone. Both evidences described the symptoms of the disorder (gaps in the skin), without discussing any underlying protein, gene, or cellular issue that could be at play (33%). Another feature of interest is that evidence 2 compares the skin layers between normal and affected individuals. Students can use this comparison as the structure of their model, essentially comparing the normal and affected individuals at the gene or protein level, and getting at the underlying mechanism. That said, *Molecular-first* students tended to take this tact (14% *M-first*, 4% *C-first*, resp.), applying evidence 1 which described a genetic change which could cause a change to protein 3.5% more often than *Classical-first* students during the *MMA*.

Model complexity during the Classical Modeling Assessment

So far, we have discussed modeling from the perspective of evidence counts as it impacts the underlying mechanism in models. Next, let's look at a typical model from each condition constructed during each assessment, starting with the *Classical Modeling Assessment*. The goal during this assessment was for students to construct a model which described the underlying biologically plausible model that explained why individuals developed a heart condition (*FHD*). We expected students to discuss why sick individuals had such combinations of alleles.

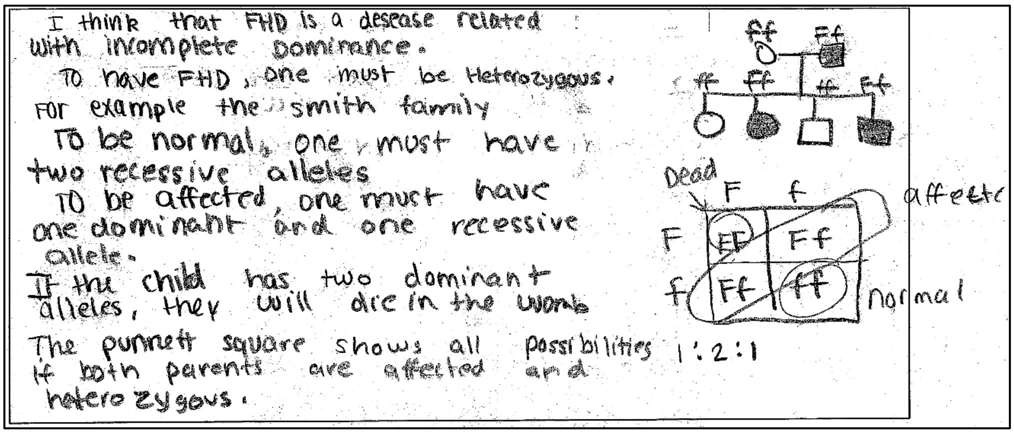

Figure 4. *Molecular-first* model constructed during the *Classical Modeling Assessment*

This first model represents a typical model constructed by *Molecular-first* condition student during the *CMA*. In this model, the student uses two of the provided evidence to describe the phenomenon presented in the assessment. First, the student describes the underlying inheritance pattern: *I think that FHD is a disease related with incomplete Dominance.* (Seen on the left, Figure 4). The student leverages evidence 3 by stating: *to be normal, one must have two recessive alleles, to be affected one must have one dominant and one recessive alleles. If the child has two dominant alleles, they will die in the womb*. The student took the evidence which described a ratio and reinterpreted this information to include a biologically plausible mechanism as well as a Punnet square (on the right, Figure 4, box drawing), which is another representation of this data. The student also reinterpreted evidence 2 (the family tree) with more information and connected this information together between these two interpretations (top right and bottom right figures, Figure 4).

Next, we look at a typical model constructed by a student in the *Classical-first* construction during the *Classical Modeling Assessment*. In this model, the student leverages evidence 2, describing the family tree at a superficial, phenomelogical level: *In evidence #2 there's a diagram that shows one of the parent having FHD which would lead to their children having FHD because the parents gives one gene from each of them to make a child* (Figure 5). The student describes the underlying story (mechanism) of inheritance when they describe the alleles (alleles are different versions of genes) and this student also draws a representation of alleles (Hh x hh, representation bottom of Figure 5).

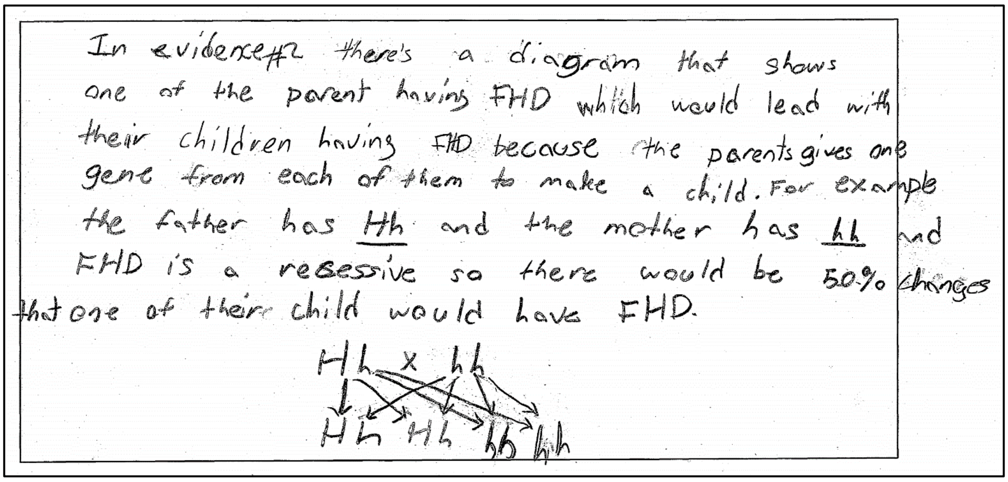

Figure 5. *Classical-first* model constructed during the *Classical Modeling Assessment*

Models constructed during the Molecular Modeling Assessment

Moving to the *Molecular Modeling Assessment*, we start with a *Molecular-first* student. The goal of this task was to construct models that explored the connection between a mutated gene resulting in a changed protein resulting in a skin disorder (*DEB*). We expected students to explain this mutated (changed) protein, make a connection between genes, proteins, and symptoms (the central dogma). The student provides a comparison between a normal and abnormal person (Figure 6). This student uses all three evidences, evidence 1 when they show the mutated gene and non-mutated gene, and normal and dysfunctional protein (on left). The student also describes *normal protein forms much of the structural component of the layer between the epidermis and dermis* (evidence 3). The student uses evidence 2 to compare normal and affected individuals at the gene and protein level, demonstrating a mechanistic explanation underlying the phenomenon.

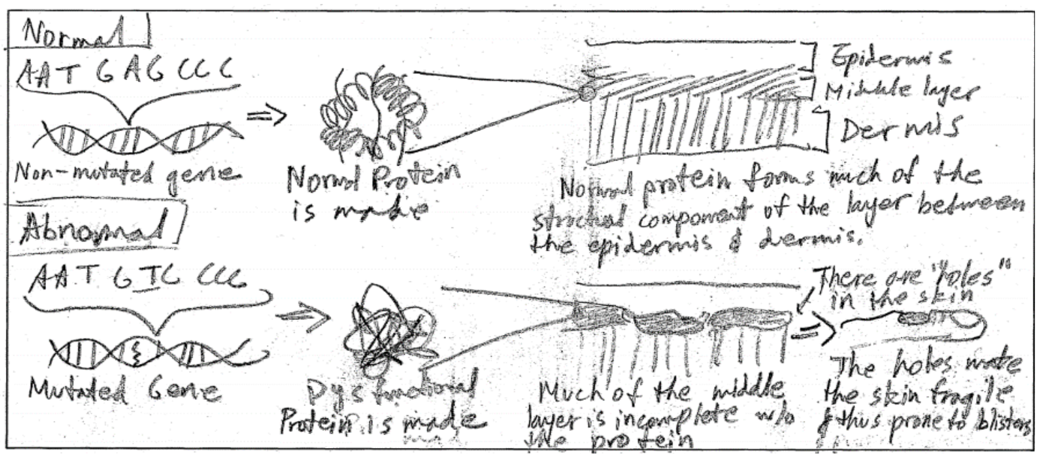

Figure 6. *Molecular-first* model constructed during the *Molecular Modeling Assessment*

We next look at a *Classical-first* student's model. This student uses all three provided evidence to compare a person with the disorder and someone who does not have the disorder, what the student refers to as normal skin and affected skin (Figure 7). The student describes the skin layers (evidence 3), and by comparing the differences in the *skin* this student is using evidence 2 as well, albeit in a superficial way. This student also uses evidence 1 to describe the underlying cause of the disorder. *This thymine is the wrong part…Because of this mutation, it's causing the skin to be fragile and dry, resulting is painful blisters.* (Figure 7, on right) This student draws the reader's attention to the mutation (changed DNA) as the cause of the symptoms of the disorder but does not discuss the underlying protein. Understanding the protein piece is central to the molecular module of genetics.

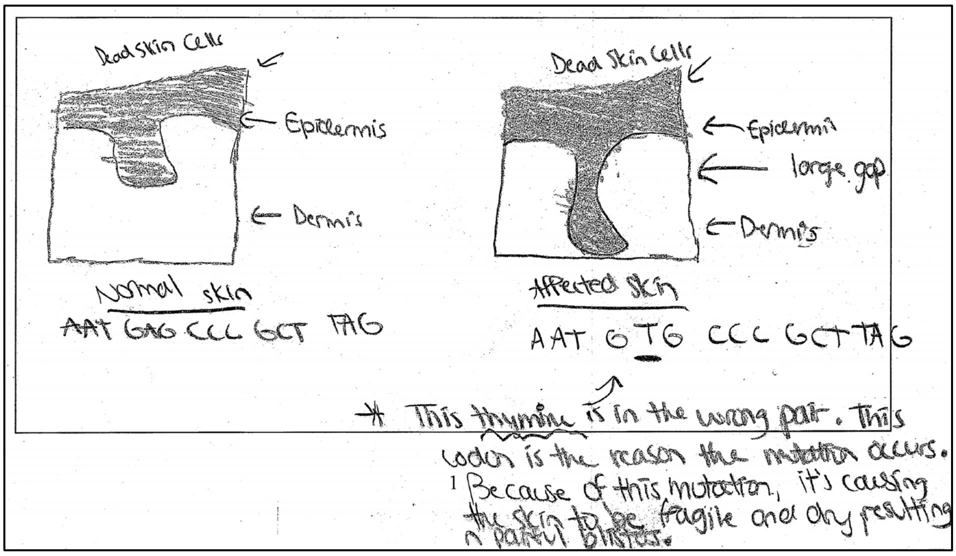

Figure 7. *Classical-first* model constructed during the *Classical Modeling Assessment*

Measures of model complexity

We see that Molecular-first students developed more mechanistic models in *both* the *Molecular Modeling Assessment* and the *Classical Modeling Assessment*. While it could be argued that students should perform better in their second modeling activity—essentially *Molecular-first* students should have a stronger showing in the *Classical Modeling Assessment* and *Classical-first* students should have a stronger showing in the *Molecular Modeling Assessment* due to a recency effect, this was not observed. *Molecular-first* students overall developed more mechanistic models in both assessments as compared to the Classical-first peers.

Similarly, we observed no evidence of student connections between the two genetics modules. Meaning, students who had completed a unit then completed the other unit did not bring knowledge from the preceding module into the following unit. For example, a *Classical-first* student did not bring knowledge of multiple generations and alleles into the *Molecular Modeling Assessment* nor did any *Molecular-first* students bring information about proteins into the *Classical Modeling Assessment*. Therefore, some aspect about the way the content was presented or relayed to students conferred a benefit to student modeling practice.

Discussion

This work extends our understanding of LPs of genetics by demonstrating that teaching molecular concepts first may support a bootstrapping effect related to modeling practice. Students in the molecular-first condition constructed models that were more mechanistic and fit with more of the provided evidence. This demonstrates a level of domain-competency and practice competency greater than that of their *Classical-first* peers. It was previously demonstrated that understanding genetic knowledge develops simultaneously and at a similar rate over time. It has also been demonstrated that a modest correlation exists between students who learned molecular genetics first with respect to learning future genetics concepts, suggesting a preparation for future learning effect. In other words, students in the *Molecular-first* condition may have experienced a bootstrapping effect for future genetics concepts (Duncan, Castro-Faix, Choi, 2016; Duncan, et al., 2017). However, we were unsure if this LP would have an impact on students' modeling practices. We wanted students to develop models which included mechanistic explanations of an underlying genetic phenomenon. While it could be argued that students built increasingly robust models in their second content modeling assessment (which was observed), overall *Molecular-first* constructed models were more mechanistic. *M-condition* students tended to use more evidence in more nuanced ways to produce more mechanistic models across both assessments. This kind of knowledge within a domain is key and helps inform how to approach and construct complex models. By noting that *M-condition* students generated models that were also more mechanistic in the *MMA* and more likely to identify the underlying content in the *CMA,* we add to this notion that learning molecular genetics first may improve not only content understanding, but also support an integration of practice with content understanding. We hope to expand these findings by exploring a follow up model evaluation task.

Expanding on how students leveraged evidence based on order of instruction helps explore the kinds of models generated by students. We noted that students generated two kinds of models as dependent on the task. In the *MMA* students generated temporal models, or those that showed how a mutated gene caused the symptoms of the disorder. Students with more mechanistic models included the protein level of the model. In the *CMA*, students constructed models that were structured as more cause-and-effect statements with more powerful models leveraging multiple evidences to explore the underlying mode of inheritance. What is key in both assessments is how students relied on at least one "hinge" evidence in a way that students can when supporting an argument (e.g., Cavera, et al., 2018; Puig, et al., 2017). Students built robust arguments simultaneously while generating models within a genetics construct.

This work demonstrates that learning molecular genetics first helps inform more mechanistic modeling practices within the domain. Stewart et al. (2005) argued that genetics literacy entails understanding both the classical and molecular models and their interrelationship. Previous genetics LPs have argued for teaching either the Classical or the molecular model first in order to support better understanding of underlying mechanisms, but less research explored the interface of content with modeling practices. Stewart et al., (2005) have argued that we need to provide sufficient and explicit opportunities for students to investigate and explain patterns of inheritance at the molecular level. Thus, supporting the bridges between the genetic literacy models is necessary to help students develop sophisticated understanding of how molecular and Classical models function. By focusing on the molecular aspect first, before moving to the more abstracted Classical piece, this may have made it possible for students to conceptualize and construct models across both domains.

University of Maryland

Abstract: Computational thinking (CT) is increasingly becoming a part of classrooms across the K-12 spectrum. While we have a sense of what it looks like for older learners to engage with CT, it is less clear what authentic CT practices look like for learners in K-5 classrooms. Part of the challenge of identifying CT in earlier grades is learners' lack of prior experience with computing and limited language to describe computational processes and practices. This study provides insights into how young learners use gestures as they engage in a set of CT-enhanced mathematics activities. This work focuses on a fourth-grade mathematics activity in which learners work to control a spherical robot as it navigates a mathematical maze. Our analysis reveals various ways that learners use gesture to complement existing virtual and physical tools available for expressing and enacting CT concepts and practices. In doing so, this work suggests both methodological and pedagogical opportunities for understanding CT with younger learners and advances our understanding of the role of gesture and embodiment as a means of supporting young learners' engagement with CT.

Introduction

Computing, and the technologies it enables, is playing a growing role in the lives of today's learners both in schools and beyond. As such, the skills, concepts, and practices associated with using computational tools to help solve problems, collectively captured under the term "Computational Thinking" (CT), are becoming increasingly important for all students to develop (Grover & Pea, 2013; Shute et al., 2017; Wing, 2006). In response to the recognition of the growing importance of CT, a growing number of efforts are seeking to bring CT into K-12 classrooms (Guzdial, 2008; Lee et al., 2014; Weintrop et al., 2016; Yadav et al., 2014). This integration takes a number of forms. One common approach for bringing CT into K-12 classrooms is the introduction of programming into curricula, either as stand-alone computer science classes or integrated into other disciplines (e.g. Franklin et al., 2020; Lee et al., 2014). A second approach to integrating CT into classrooms focuses less on having learners author programs and instead has learners interact with technological tools to help deepen disciplinary learning. This can include computational models and simulations, data analysis and visualization software, or physical computing kits or robots (Bers et al., 2014; e.g. Brady et al., 2015). A third approach to bringing CT into classrooms relies on unplugged activities where learners employ CT concepts and practices but do so without direct interaction with a computational device (e.g. Brackmann et al., 2017). Central to all three of these CT integration approaches is providing opportunities for learners to enact CT practices and communicate with and about CT ideas. In each of these forms of CT integration, what it looks like to engage with CT differs.

In older grades, where learners have more prior computational experiences and a larger vocabulary to express computational ideas, identifying authentic use of CT practices can focus on the ways learners express their ideas verbally, written, and in the computational artifacts they produce. In earlier grades, where learners have little or no prior experience with programming and relatively limited experience with computational devices and software tools, it becomes more difficult to identify CT concepts enacted based on verbal explanations, written responses, or the artifacts produced during the learning activity.

Building on work investigating how learners navigate the interconnectedness of STEM learning grounded in the embodied, material, social, and cultural contexts in which learning occurs (Jordan & Henderson, 1995; Kozma, 2003), this work explores the embodied ways that learners move and gesture as a means to express and communicate CT concepts. For this work, we ground our conceptualization of CT in the PRADA (pattern recognition, abstraction, algorithms, and decomposition) framework (Dong et al., 2019). In attending to learners' embodiment of CT ideas and practices, we can see younger learners' reason about CT concepts and employ CT practices as a means to solve problems that would otherwise not be noticed if focusing on only verbal explanations or external representation (e.g. authored programs). In doing so, this work shows how an embodied perspective can serve as a useful analytic approach for identifying and understanding CT practices in younger learners. At the same time, supporting teachers in attending to gesture and action in CT activities can serve as a productive pedagogical approach for nurturing seeds of CT as they begin to take shape with younger learners.

To explore how young learners embody CT ideas, this paper presents data from the implementation of a fourth-grade CT-enhanced mathematics curriculum based around the Sphero robot (Bih et al., 2020). In particular, we present two vignettes of learners working to write short programs to get the Sphero robot to navigate a maze composed of prime and composite numbers. Through these vignettes, we show how an embodied lens reveals ways learners reason about and employ CT concepts and how they use their bodies as a means to communicate CT ideas. Specifically, we show how one learner enacts iterative logic through repeated gestures and how a second learner uses her own body as a resource for figuring out how to computationally encode her desired intentions into a computational form for her robot to execute. This work contributes to our understanding of the form that CT can take in K-5 classrooms and seeks to help equip teachers and researchers to better identify and support embodied enactments of CT in their work.

This paper continues with a discussion of the literature this work draws from before discussing the context in which the study took place and the methodological approach used. We then present a pair of vignettes showing how an embodied lens can reveal the ways that fourth-grade learners engage with and communicate about CT through the use of their bodies. Finally, we discuss the implications of this work, the contribution it makes to the literature on embodiment and CT, and share the next steps for this line of inquiry.

Prior work

Computational thinking in elementary grade classrooms

One of the central contributions of Papert's work was showing that computers can serve as powerful tools to support learning and that this context for learning can be effective for younger learners (Papert, 1980, 1993). Papert and colleagues' work on Constructionism laid the groundwork for what is now called Computational Thinking (Wing, 2006). CT is a term used to capture the concepts, practices, and skills one uses in order to effectively solve problems using computational tools, such as developing algorithms, decomposing problems, and debugging solutions (Grover & Pea, 2013; Shute et al., 2017). The last decade has seen a significant amount of research on CT including work looking to integrated CT into other disciplines (e.g. Barr & Stephenson, 2011; Israel & Lash, 2019; Peel et al., 2019; Sengupta et al., 2013; Settle et al., 2012; Weintrop et al., 2016; Wilensky et al., 2014) as well as work seeking to understand how to support younger learners in engaging in CT.

The idea that the concepts and practices associated with CT can be powerful for learning other disciplines has a long history dating back to early work by Papert (1972) on Logo and mathematics and diSessa (1982) and physics. In both cases, programming was used as a means to explore disciplinary concepts. A central premise for this integration is the potentially mutually supportive nature of CT and disciplinary content: that CT provides a way to deepen disciplinary learning while at the same time, disciplinary learning can provide a meaningful context to employ CT concepts and practices (Bih et al., 2020; Sengupta et al., 2013; Weintrop et al., 2016).

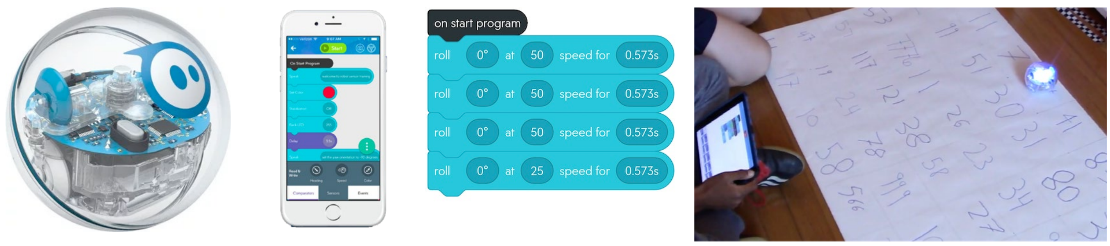
As part of exploring the potential of CT across the curriculum has included investigating what CT might look like with younger learners. Two common approaches for bringing CT into K-5 classrooms are unplugged activities and the use of robotics toolkits. Unplugged activities allow learners to explore and enact CT concepts without using a computer, often having the younger learner act out computational processes such as algorithms or employ computational ideas such as iteration (Brackmann et al., 2017; Curzon et al., 2014; Jagust et al., 2018). Alongside unplugged activities, robots and robotics toolkits have also been used in elementary classrooms to introduce younger learners to CT concepts (Angeli & Valanides, 2020; Bers et al., 2014; Chalmers, 2018).

Embodied cognition

The second body of literature this work draws on is embodied cognition. Cognitive scientists and learning scientists have long explored various aspects of the relationship between thinking and embodiment (Abrahamson & Lindgren, 2014; Wilson, 2002). In mathematics learning research, the role of embodied cognition and its utility as a lens to understand mathematical learning has been well developed (Nunez et al., 1999; Williams-Pierce et al., 2017). In particular, research has identified how gestures can provide mathematical reasoning information not contained in the accompanying speech (Pier et al., 2019), and can mediate abstractions and communication gaps in cases where language verbalization is a challenge (Nathan et al., 2013; Ng, 2016). Attending to gesture in multimodal environments can be particularly productive, as mathematical representations take on a wide variety of forms, and threading through those forms becomes a crucial component of the learning environment (Nathan et al., 2017). This work has led us to consider the potential of bringing an embodied perspective to research on the interactions that occur in technology-enhanced multimodal learning environments (Kirsh, 2013; White & Pea, 2011). Given the overlap between mathematical and computational thinking (Shute et al., 2017), this body of research suggests the generative potential for bringing an embodied lens to understanding CT learning.

Methods and participants

This work was conducted in a fourth-grade mathematics classroom in an urban school district in the Mid-Atlantic region of the United States. The activities reported in this paper are part of a curriculum developed through a Research-Practice Partnership (RPP) (Coburn et al., 2013) with the district. The RPP includes education and technology researchers working alongside elementary mathematics teachers and district-level computer science administrators. To collect this data, we worked closely with a focal fourth-grade teacher, observing her classroom as she taught a CT-enhanced lesson plan that asked learners to use the Sphero robot (Figure 1a) to explore mathematical concepts. The Sphero is a spherical robot that can be programmed on a tablet or smartphone (Figure 1b) using either block-based or text-based commands. In the focal activity for this work, learners wrote block-based programming primarily using the roll command to define the robot's movement (Figure 1c).



(a) (b) (c) (d)

Figure 1. (a)The Sphero robot, (b) programming environment, (c) sample Sphero program, and (d) two students working on their prime number path program.

The lesson that we focus on for this work is entitled *Prime Number Path*. As part of this lesson, students were asked to design a grid on a large sheet of paper that contained prime and composite numbers interspersed and included a "path" from one side to the other composed only of prime numbers (Figure 1d). Students then were tasked with programming the Sphero robot to navigate the prime number path. After completing their activities, teams exchanged their grids with other teams and then find and program the prime number mazes designed by their peers.

This work took place in a racially diverse (51% White, 17% Latinx, 15% Black, 9% Asian, 8% Mixed Race) school where 19% of the students in the school are designated as English Language Learners. The class included 21 students working in pairs with one Sphero and one iPad per pair. The lessons we observed were taught in the final month of the school year. By that point, students were familiar with the structure of Sphero.Math activities and had experience working with the Sphero robots. For data collection, the teacher selected two pairs of students to serve as focal groups. These groups were asked to work outside of the classroom to decrease ambient noise and ensure non-consenting students were not captured on video.

Data and analysis approach

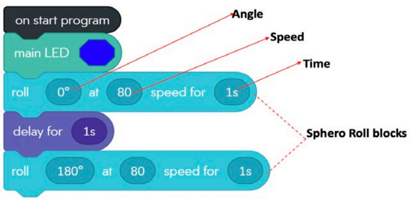
For each focal pair, we set up a stationary tripod to record them working through the activities. Additionally, each student wore a head-mounted camera to provide a student-centric perspective of the activity. This resulted in three video streams for each pair as they worked through the activities. Students were occasionally asked questions by the researchers as they worked to understand their thinking and how they were approaching the assignment. Along with the videos collected, at the end of the activity, the researchers asked the students to describe their experiences with programming the robot and complete the task. The videos were systematically analyzed for CT and mathematics engagement with a particular focus on the ways learners employed embodied practices to communicate and engage with CT. Video clip segments of instances where students engaged in embodied practices were identified and transcribed using interaction analysis methods (Jordan & Henderson, 1995).

Findings

In this section, we present two vignettes of learners showing the ways gesture served as a resource for engaging with and expressing CT ideas. In particular, we present a vignette showing how learners used gesture as a means of expressing iterative logic and the learners' use of their bodies as a resource to problem solve how to express their intentions with the Sphero.

Gesturing iterative logic

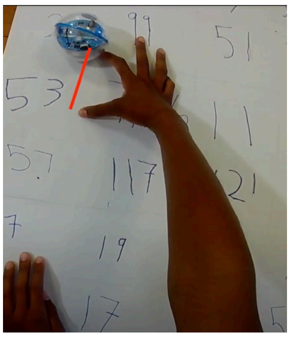
To make the Sphero move, the students have to enter numerical arguments into the field of the `roll` block (Figure 2a) by defining the direction (angle), speed, and duration (in seconds) for the movement. Changing how far the Sphero will roll can be done by modifying the speed input, the duration input, or both. Our first vignette focuses on how one pair of learners navigated this aspect of controlling the Sphero.

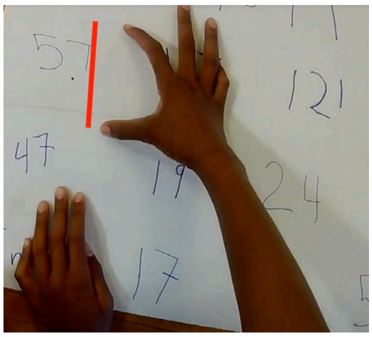


(a) (b)

Figure 2. (a) A Sphero Block program showing direction, speed, and time; (b) the software interface to select time speed and direction.

Early in the activity, the focal participants for this analysis tried to agree on which variable to manipulate to make their Sphero navigate their prime number maze. Student 1 says: *"we need more seconds or speed, like speed"*, and then Student 2 replies, *"no seconds, seconds"*. As the students debate on what adjustments to make on the time, Student 1 says *"do 1 second 'cause you know that's not gonna get you very far from what the next square"*. Student 1 then says, *"maybe try 1.20"*, again, suggesting modifying the duration as a means to change the distance traveled. Instead of changing the duration input, student 2 places her thumb at the place the robot started and her index finger at the location where the Sphero stopped (Figure 3a) and says *"so this is a second"*. In doing so, she has created a measurement of how far the robot travels in one second. She then holds her hand in the fixed position, and moves it from the start location to the square she wants the Sphero to roll to and quietly counts to herself *"two, three"*. In this way, she is using her hand as a unit of measure and maintaining the same hand position between each space separating the numbers as a means to calculate how many times the motion must be repeated to arrive at the desired square.





(a) (b)

Figure 3. Measuring gestures to represent repeated iterations of the time and distance it will take for the Sphero to travel from one number to the next.

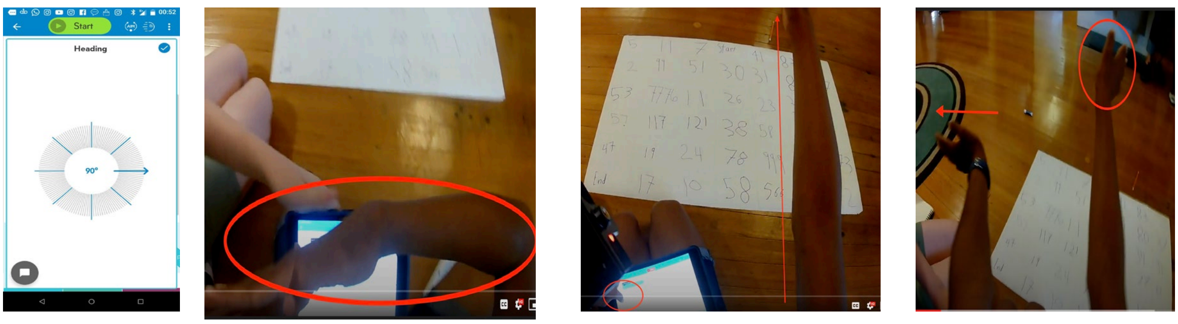
In this vignette, we see gesture accomplishing two goals for the student. First, she uses her hand as a means for defining how far the robot will travel given a set of inputs. More specifically, she uses her hand as a way to translate the virtual command: `roll 0° at 80 speed for 1s` into a specified distance in the physical world and does so in a way that is visible and accessible to her partner. Here, gesture is serving as a cognitive scaffold for concretizing a specific movement command while also serving a communicative role between two partners working to solve a programming challenge. The second role that gesture is providing to support CT is to facilitate the enactment of iterative logic. As a means to inform her algorithm design, she moves her hand, one step at a time, to count the number of times the already-defined roll command should be repeated. In computer programming, iterative logic is an important programming construct frequently used to develop algorithms for computers to execute. In using gesture to quantify distance, the learner is acting out the repeating logic, using her hand and the physical space to scaffold the construction of her program.

This episode shows how this student is embodying her robot's motion as a means to facilitate developing a successful algorithm for her robot navigating the prime number path. Notably, the student never verbalizes this repeating logic or vocalizes her thought process. Instead, gesture is serving as both a way to support her reasoning and communicate computational behaviors. This communicative role is significant for younger learners who may not have the vocabulary to articulate programming concepts or prior experience describing process. Through action the learner demonstrates a central CT concept that had not yet been articulated verbally or symbolically, suggesting gesture served as the initial pathway into engagement with the concept.

Embodiment as a CT problem-solving tool

In the second vignette, we focus on how students work to understand the geometry involved in making the Sphero robot navigate the Prime Number Path (Figure 1d) and the ways in which they translate the physical movement of the robot into a set of commands to control the robot. To enter an angle into the Sphero programming interface, the application presents the user with a 360° protractor with an arrow denoting the selected value (Figure 4a). One challenge of programming physical objects from a virtual interface for young learners is the translation of direction from the physical world onto the 2-dimensions protractor on the interface. This is especially challenging given the orientation of the protractor on the screen is fixed, so when you rotate the tablet, the relationship between direction on the tablet and the real-world changes (i.e. it does not update like the compass on a smartphone). In order to navigate this translation, the learners in our study mapped the coordinate geometric systems of the tools (the angle on the virtual interface and the robot's physical position) onto themselves and used their bodies to ground the meaning of the angles. This kind of sense-making between representations was seen repeatedly as the students navigated this activity. Gesturing was a central grounding and communication resource used by the learners as they translated the geometric angles from virtual to physical contexts of the Sphero.

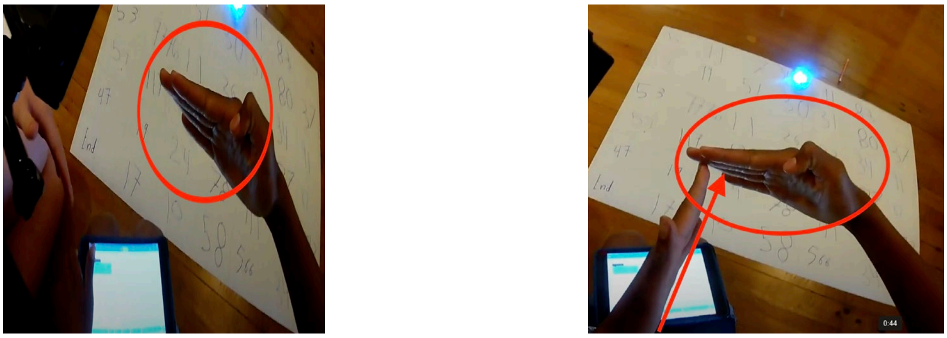
In analyzing the Prime Number Path activity, we can see how embodiment is used by learners to navigate representational contexts and make progress towards computationally expressing their intentions. One such example was seen as the students tried to input the values to define the directional angle through the protractor interface. This episode begins with Student 2 pointing and gazing at the protractor on the iPad (Figure 4a), and then bending her right elbow in front of her for a few seconds without saying a word (Figure 4b). After a few seconds of maintaining her gaze and elbow in that position, she goes ahead and stretches out her right arm in front of her (Figure 4c) and then says *"this is, this way for 90!"* and Student 1 cuts in saying *"so we have to make it go ..."* but Student 2 continues slowly as if in doubt, *"this is this way for 90* [maintaining her arm raised in front of her and gazing into the software protractor] *and we need to make it go... this way"*, gradually raising her left arm to the same level as her right arm, with now both arms raised and stretched parallel in front of her (Figure 4d). She then says *"that means it's going to go… So we need to make it 270"*. This verbal confirmation of what to do next, sheds light on the thought process she was going through in her series of gestures, ultimately helping her figure out what values to input into the program to get the Sphero to roll in the desired direction.



(a) (b) (c) (d)

Figure 4: (a) The Sphero interface for inputting angle and (b-d) a series of sequential images of student reasoning through directions and angles to program her Sphero.

As the group continues to work on writing the program to navigate the maze, they return the Sphero to the starting square to test out their new directions. Before running the program, Student 2 tests her logic again, saying *"so zero* [with her right palm curved in front of her face (Figure 5a)] *so it needs to go this way"* and then curves her left palm to meet up with her right palm at a right angle (Figure 5b), saying *"this is 270!"*. From Student 2's verbalization and interactions with this environment, we know that she is using both arms to represent some of the interactive tools in this environment. Her left hand is representing the robot, while her right hand represents the directional angle the robot will have to make. In this instance, the learner is trying to navigate between the Sphero moving in the physical world and the need to express commands programmatically in the virtual world. To do this, she is grounding both the abstract representation of the angle and the concrete position of the robot through an embodied practice which she maps onto her body. In this way, she uses her body to mediate the transition from the physical, three-dimensional world to the virtual two-dimensional programming interface. As such, her body is serving as a resource to facilitate computational thinking and mediate the act of programming.



(a) (b)

Figure 5: (a) A student reasoning with her body about how to program her Sphero, using her right hand to denote the Sphero's positions (b) and then having her left hand interact with her right as a means to understand what the desired angle should be.

Discussion and conclusion

This paper attends to the ways that learners use their bodies to embody computational ideas, which in turn, helps them make progress on computational problems. In doing so, this work adds to both the CT and embodied cognition literature by showing how embodied resources can be used to express CT concepts while also showing how CT can serve as a productive venue for identifying ways learners engage with new computational ideas that they may not have the verbal or symbolic language to otherwise express. It is common practice in mathematics to embody distances by measuring with parts of our bodies, like our feet or arms, or to use gestures to move across different modalities within a single learning context (e.g., Nathan et al., 2017). In the first vignette, the students embody distance but are using it to represent time as the Sphero's distance is defined by speed and time. They then repeatedly apply that distance as a means of enacting iteration. In the second vignette, embodiment is used as a means of moving between the physical world (i.e. how the Sphero will move), mathematical quantification of the space (i.e. identified the desired angle of travel), and expressing that intention in a computationally meaningful way (i.e. programming the robot to carry out the desired command). This shows how embodiment serves as a resource for learners as they work to solve computational problems.

This research shows how embodiment is a particularly productive resource for young learners who may lack the technical language or representational knowledge to express ideas related to programming and process in other ways. This can be seen in how iteration was embodied in the first vignette. This article argues that gestures and embodiment support students' CT and can ground students' understanding and expression of CT concepts. Further, the fact that the Sphero robot executes programs in the physical world provides a natural invitation for learners to draw on their embodied resources in trying to make sense of CT concepts and employ CT practices, as we saw in the second vignette. In bringing an embodied lens to this work, we begin to see and make sense of the hidden patterns of CT happening in ways that would be missed if we focus solely on verbal utterances or written artifacts. Throughout the Sphero activities, students were able to interact with the learning environment in novel ways that helped deepen their understanding of mathematical and CT concepts. Such embodied practices support the argument that integrating CT practices early on for young learners is a valuable addition to problem-solving skills students need to learn (Wing, 2006; Grover & Pea, 2013).

One implication of this work is identifying the importance and potential for researchers and teachers attending to how students use their bodies as a means to engage with CT. Additionally, it highlights the generativity of robots as a pathway into CT for younger learners. While this generativity is certainly not a new idea (e.g. Papert, 1980), recognizing the same powerful ideas are present with the latest generation of robotics toolkits that are being used in classrooms can serve as an important reminder and help connect earlier work on the topic to contemporary practices.

As computational thinking continues to grow in importance, it is important we support all learners, especially younger learners, in engaging with the concepts and practices. While older learners will have more experience with mathematical and computational representational systems and a larger vocabulary with which to articulate their thinking, younger learners find alternative ways to express and engage with CT. In particular, this work shows how younger learners draw on embodied resources as a means to productively enact CT practices and employ CT concepts. In highlighting the role of embodiment in young learners' CT practices, we shed light on one form of early CT so as to help equip researchers and educators to identify and support the CT that is happening with younger learners and further support the larger goal of bringing CT to all learners.

Fostering Students' Cue Utilization in a Productive Failure Setting

Ruhr-Universität Bochum

Abstract: Productive Failure (PF) with problem solving prior to instruction has been shown to have beneficial effects on learning, at least in STEM domains. It is hypothesized to be fundamental for the effectiveness of PF that learners become aware of their failure during problem solving. Developing this failure awareness seems to be harder for PF students who learn in certain non-STEM domains. To support PF students' development of failure awareness while learning in a non-STEM domain, this quasi-experimental study implemented and tested a cue-utilization activity prior to instruction. Our results show that PF students who experienced the cue-utilization activity still did not more critically evaluate their solution ideas and did not acquire more knowledge about social science research methods than their counterparts in a PF condition without cue-utilization activity. These results are discussed in light of students' epistemological beliefs about social sciences.

Introduction

Over the last decade research on Productive Failure (PF) has been thriving. The PF approach combines two successive learning phases: (1) an initial problem-solving phase and (2) a delayed instruction phase. During the problem-solving phase students are asked to (often collaboratively) generate different solution ideas for a novel and complex problem (e.g. Kapur & Bielaczyc, 2012). Due to this novelty and complexity of the problem, most students struggle or even fail to solve the problem canonically. However, this failure is assumed to prepare students for learning the targeted concepts during subsequent instruction (e.g. Kapur, 2016). For this purpose, the delayed instruction phase should compare and contrast the critical features of students' erroneous solution ideas with the components of the canonical solution (e.g. Loibl & Rummel, 2014a). Many studies have shown beneficial effects of PF on students' acquisition of conceptual knowledge (for reviews see, e.g. Kapur, 2015; Loibl, Roll, & Rummel, 2017). It stands out that most of these studies have focused on investigating student learning in STEM (i.e., science, technology, engineering, and mathematics) domains, especially mathematics (e.g. Kapur, 2012; Loibl & Rummel, 2014a). Only a few studies have examined the effect of problem solving prior to instruction on student learning of domain-general skills (e.g. Matlen & Klahr, 2014; Kant et al., 2017) or in non-STEM-domains (e.g. Glogger-Frey et al., 2015; Nachtigall, Serova, & Rummel, 2020). However, those studies were unable to demonstrate beneficial effects of PF or problem-solving prior to instruction approaches more generally on students' knowledge acquisition.

What PF students in non-STEM or domain-general learning contexts seem to be lacking is a reflective view on their own knowledge. Metacognitive competencies, such as monitoring one's understanding, realizing that one is missing an important piece of information, and identifying that piece of information, are hypothesized to be crucial for successful learning in PF settings (Loibl et al., 2017). For instance, findings by Loibl and Rummel (2014a, 2015) suggest that the PF effect on students' learning in mathematics is linked to PF students' awareness of knowledge gaps and their experience of their competence limitations. PF students' failure awareness is expected to prepare students for successful learning during instruction (Loibl et al., 2017). Specifically, when learners realize their knowledge gaps, their mental model is challenged and they may develop a desire to fill their gaps in order to modify their mental model (e.g., Tawfik, Rong, & Choi, 2015). However, in certain domain-general or non-STEM learning contexts, PF students appear to have difficulties with becoming aware of their knowledge gaps, their competence limitations, or their failure more generally. For instance, Kant, Scheiter, and Oschatz (2017) as well as Matlen and Klahr (2014) hypothesize that the non-effects of problem solving prior to instruction on learning the domain-general CVS (i.e., Control of Variables Strategy) in their studies may be due to the fact that their participants were unable to develop an awareness of their failure prior to instruction. That is, students who design experiments in order to learn the CVS receive no feedback on the quality of their performance through their developed designs, while students who work on mathematical problems (as in typical PF studies) can more easily encounter whether their solutions are correct or not. Moreover, two studies conducted by Nachtigall et al. (2020) demonstrated that PF students – in a non-STEM learning setting – reported significantly higher perceived competence than their counterparts in a Direct Instruction condition although they failed to solve a novel and complex problem during the problem-solving phase. Both studies demonstrated non-effects of PF on student learning of social science research methods, and this non-effect may be caused by PF students' lack of failure awareness prior to instruction (Nachtigall et al., 2020).

Against this background, supporting PF students' monitoring of their own understanding and their accurate judgements of their competence during the initial problem-solving phase appears necessary in order to promote the effectiveness of PF for learning in non-STEM-domains. One reason for students' difficulties with regard to accurately monitoring their learning and assessing their competence may be related to their use of inappropriate cues. According to the cue-utilization framework, "participants do not monitor directly the strength of the memory trace of the [study] item in question [in order to assess their learning and knowing], but use a variety of cues that are generally predictive of subsequent memory performance." (Koriat, 1997, p. 350). However, these cues differ with regard to their predictive accuracy of students' actual learning, and students tend to use pervasive cues, such as time on task or perceived difficulty of learning materials (e.g., de Bruin, Dunlosky, & Cavalcanti, 2017). For instance, if the learning material is easy to process, students often tend to judge their learning or their performance based on their perceived difficulty of the learning materials and not on their actual achievement (de Bruin & van Merriënboer, 2017). In order to accurately monitor their own knowledge, learners need to use diagnostic cues (de Bruin et al., 2017). But, learners are often unable to utilize diagnostic cues on their own. It then becomes necessary to provide external support in order to foster learners' accurate self-evaluation (de Bruin et al., 2017).

However, providing PF students with external support, namely with explicit guidance by the instructor during the initial problem-solving phase has been demonstrated to be either less effective (Kapur, 2012) or equally effective (Loibl & Rummel, 2014b) than withholding any guidance for PF students' knowledge acquisition. To foster PF students' utilization of diagnostic cues and, thus, their learning it may be more promising to provide students with implicit feedback on the quality of their generated solutions, such that students can encounter their specific knowledge gaps on their own. One method could be to confront PF students with a worked example prior to instruction. Studying worked examples reduces cognitive load, helps students to focus their attention on the problem state, and may increase learning outcomes, especially of novice learners (Sweller et al., 1998; Kant et al., 2017). When studying a worked example, learners can compare their own performance to the performances of experts that worked on the same content. This comparison could lead learners to monitor their understanding and competencies in a more elaborated way. Newman and DeCaro (2018) as well as Glogger-Frey et al. (2015) found that studying worked examples prior to instruction is indeed more effective for students' learning than trying to solve a problem prior to instruction as in PF. Therefore, it may be promising to implement the beneficial effects of worked examples into a PF setting in order to support students' utilization of diagnostic cues and consequently their learning in non-STEM-domains. More specifically, asking PF students to compare their often erroneous solution ideas to a worked example prior to instruction could help them to use diagnostic cues for assessing their competence and learning. Thereby, PF students may develop an awareness of their knowledge gaps prior to instruction and be better prepared to learn or to fill their gaps during instruction. To test these hypotheses is the goal of the present study.

The present study

The present study aims at investigating whether fostering PF students' utilization of diagnostic cues by having them study a worked example prior to instruction leads to beneficial effects on both students' awareness of their failure and their learning in a non-STEM domain, namely social science research methods. Specifically, we investigate the following two research questions (RQ):

RQ1: Does a cue-utilization activity (i.e., studying a worked example) prior to instruction help PF students to use diagnostic cues for assessing their problem-solving performance such that they become aware of their failure?

RQ2: Does a cue-utilization activity (i.e., studying a worked example) prior to instruction have an impact on PF students' learning of social sciences research methods?

To investigate these research questions, we conducted a quasi-experimental study comparing two conditions: (1) Productive Failure (PF): Students try to solve a problem prior to instruction, and (2) Productive Failure with *cue-utilization activity* (PF_{cue}): Students try to solve a problem and are asked to compare their solution attempts to a worked example prior to instruction. Building on the cue-utilization framework, research on the worked-example effect, and the findings of PF studies indicating that PF students in domain-general or non-STEM settings may not become aware of their failure during problem solving due to the lack of feedback (Kant et al., 2017; Matlen & Klahr, 2014; Nachtigall et al., 2020), we hypothesize that PF_{cue} students report lower perceived competence (Hypothesis 1/H1) and a higher awareness of knowledge gaps (Hypothesis 2/H2) prior to instruction than PF students. Consequently, we further assume that PF_{cue} students outperform PF students on a posttest assessing their knowledge about social science research methods (Hypothesis 3/H3).

Method

Participants

80 10th and 11th graders (Age: $M = 15.76$, $SD = 0.77$; 58% female) from four social and educational science classes of four German secondary schools participated in the present study. We implemented a quasi-experimental design and randomly assigned the classes to the experimental conditions as a whole. Specifically, two classes (n = 42) were assigned to the PF condition and two classes (n = 38) to the PF_{cue} condition.

Experimental design and procedure

The learning topic related to social science research methods, namely the differences between causal versus correlative empirical evidence within the social sciences. To teach students the topic of causal versus correlative evidence, we used the same learning materials (i.e., two problem-solving tasks and an instructional lesson) as in the study conducted by Nachtigall et al. (2020).

Students in both conditions experienced an initial problem-solving phase (learning phase 1), a delayed instruction phase (learning phase 2), and a final practice phase (learning phase 3). During the initial problem-solving phase, students in both conditions had to work in groups of three to four on the same task. The task asked them to think about the possible results that could be derived from a certain study on the relation between teenager’s consumption of video games that displayed aggressive actions and their own aggressive behavior after playing those games. Students received information on the design of the study (namely a longitudinal study with one group) and the following researchers’ hypothesis: ‘Teenagers show more aggressive behavior, because they play more video games that display aggressive actions.’. Specifically, students were asked (a) to think of possible outcomes of the study, (b) to decide which of those possible outcomes was most likely to be found, and (c) to decide whether and explain why one of the possible outcomes could confirm or reject the researcher’s hypothesis. During the delayed instruction phase in both conditions, the same experimenter explained that a longitudinal study with one group (as described in students’ previous task) offers only correlative evidence and why correlative evidence cannot be interpreted as causal. During the final practice phase, students had to work individually on an isomorphic task.

The only difference between the two conditions relates to the cue-utilization activity (learning phase 1.1), implemented in the PF_{cue} condition. After the initial problem-solving phase, PF_{cue} students were asked to collaboratively compare their solutions generated in the group to a worked example and to write down the respective similarities and differences. The worked example included the information of the instructional lesson.

After each learning phase, we administered questionnaires (three questionnaires in the PF condition and four questionnaires in the PF_{cue} condition) to assess our control and process variables. At the end of the experiment, a posttest assessed students’ knowledge about the targeted learning concept. Table 1 shows the experimental procedure in both conditions.

Table 1: Overview of the experimental design

Learning phase	**Test phase**	**PF condition**	**PF_{cue} condition**
	1	Questionnaire 1	
1		Collaborative problem solving	
	2	Questionnaire 2	
1.1			Cue-utilization activity
	2.1		Questionnaire 2.1
		Break	
2		Instruction	
3		Individual problem solving (practice phase)	
	3	Questionnaire 3	
		Break	
	4	Posttest	

Measures

As previous PF studies (e.g. Kapur, 2014, Nachtigall et al., 2020) demonstrated that *students' grades* affect their learning outcome, the first questionnaire measured students' grades as a control variable by asking them to indicate their grades in three different subject areas (i.e. social/educational sciences, German language, and mathematics).

The questionnaires administered after the learning phases 2, 2.1 (only in PF_{cue}), and 3 assessed students' *perceived competence* and their *knowledge gaps*. For assessing students' perceived competence, we used the short scale of intrinsic motivation developed by Wilde, Bätz, Kovaleva, and Urhahne (2009). The questionnaire includes the following three items on perceived competence: (1) I am satisfied with my performance during this learning phase; (2) I was skilled in the activities during this learning phase; (3) I think I was pretty good at the activities during this learning phase. The internal consistency of the subscale for perceived competence was satisfactory (after learning phase 1: Cronbach's $\alpha = .81$, after learning phase 2.1: Cronbach's $\alpha = .88$, after learning phase 3: Cronbach's $\alpha = .83$). For measuring students' knowledge gaps, we used five items (e.g. "I lack knowledge required to solve this problem") adapted from Loibl and Rummel (2014a) and Glogger-Frey et al. (2015). The internal consistency of these items was again satisfactory (after learning phase 1: Cronbach's $\alpha = .76$, after learning phase 2.1: Cronbach's $\alpha = .82$, after learning phase 3: Cronbach's $\alpha = .77$). All items for assessing students' perceived competence and their knowledge gaps rated from 1 (*strongly disagree)* to 5 (*strongly agree*).

A posttest with eight items assessed students' ability to reproduce, apply, and transfer the contents of the instructional lesson by asking them to individually solve familiar as well as unfamiliar problems. The total score of the posttest ranged from 0 to 21. Two raters coded 100% of the dataset and reached a high agreement ($ICC_{absolute} = .95$; 95%-CI [.92, .97]). Disagreements were resolved through discussion, such that we were enabled to use one dataset for further analyses.

Results

Prior analyses

Before testing our hypotheses, we investigated whether PF and PF_{cue} students differed with regard to their reported grades. We conducted a MANOVA with condition as factor and the three grades as dependent variables. There were no significant differences between the two conditions in the three reported grades (educational/social sciences: $M_{PF} = 2.04$, $SD_{PF} = 0.70$, $M_{PF+CUE} = 2.18$, $SD_{PF+CUE} = 0.95$, $F(1, 74) = 0.49$, $p = .49$, $\eta p^2 = .007$; German language: $M_{PF} = 2.33$, $SD_{PF} = 0.72$, $M_{PF+CUE} = 2.59$, $SD_{PF+CUE} = 0.74$, $F(1, 74) = 2.28$, $p = .14$, $\eta p^2 = .030$; mathematics: $M_{PF} = 2.36$, $SD_{PF} = 1.14$, $M_{PF+CUE} = 2.35$, $SD_{PF+CUE} = 1.04$, $F(1, 74) = 0.00$, $p = .99$, $\eta p^2 = .000$).

Confirmatory analyses

To test H1 (i.e., PF_{cue} students report lower perceived competence than PF students prior to instruction) and H2 (i.e., PF_{cue} students report a higher awareness of knowledge gaps than PF students prior to instruction), we conducted a MANOVA with condition as factor and students' perceived competence and their reported knowledge gaps prior to instruction (i.e., after problem solving in the PF condition and after the cue-utilization activity in the PF_{cue} condition) as dependent variables. The analysis reveals no significant effect of condition neither on perceived competence ($F(1,78) = 1.31$, $p = .26$, $\eta_p^2 = .017$, 90% CI [.000; .089]) nor on reported knowledge gaps ($F(1,78) = 1.08$, $p = .30$, $\eta_p^2 = .014$, 90% CI [.000; .083]). Hence, against our hypotheses, students' perceived competence and their reported knowledge gaps do not differ significantly between the two conditions (see Table 2 for descriptive statistics).

Table 2: Descriptive statistics for students' perceived competence and knowledge gaps prior to instruction

	PF ($n = 42$)	**PF_{cue}** ($n = 38$)
	M (SD)	***M (SD)***
Perceived competence	3.57 (0.59)	3.39 (0.85)
Knowledge gaps	2.41 (0.66)	2.58 (0.80)

To test H3 (i.e., PF_{cue} students reach a higher learning outcome than PF students), we conducted an ANCOVA with condition as factor, posttest performance as dependent variable, and an average score of student grades as covariate (due to significant correlations with students' posttest performance). Against our H3, the ANCOVA reveals no effect of condition ($F(1,78) = 0.33$, $p = .57$, $\eta_p^2 = .004$, 90% CI [.000; .057]). Thus, PF_{cue}

students (M = 8.29, SD = 3.49) did not outperform PF students (M = 8.79, SD = 3.34) on a posttest assessing for knowledge about correlative versus causal evidence.

Exploratory analyses

As none of our hypotheses could be confirmed, the question arises why the cue-utilization activity did not have any impact on students' awareness of their knowledge limitations. To investigate this question, we conducted further exploratory analyses.

We first took a closer look at the development of PF_{cue} students' perceived competence and their reported knowledge gaps across the problem-solving phase, the cue-utilization activity, and the instruction and practice phase. We expected that the cue-utilization activity would help students to become aware of their failure and their knowledge limitations. Thus, the cue-utilization activity should lead to a decline of students' perceived competence and an increase of their awareness of knowledge gaps. After the explanation of the canonical solution during instruction and after practicing, students' perceived competence should increase again, and their reported knowledge gaps should decrease. To investigate these assumptions, we conducted two repeated-measures ANOVAs with the three times of measurement of perceived competence or reported knowledge gaps as within-subjects-factor. For PF_{cue} students' perceived competence, the analysis reveals a small but not significant effect of time of measurement ($F(1.66,61.82) = 2.11$, $p = .14$, $\eta_p^2 = .05$). For PF_{cue} students' reported knowledge gaps, the repeated-measures ANOVA reveals again a small but non-significant effect of time of measurement ($F(1.46,54.09) = 1.29$, $p = .28$, $\eta_p^2 = .03$). Thus, neither PF_{cue} students' perceived competence nor their reported knowledge gaps did differ significantly between the three times of measurement (see Table 3 for descriptive statistics).

Table 3: Descriptive statistics for PF_{cue} students' development of perceived competence and knowledge gaps

		M (SD)
Perceived competence	after problem solving	3.46 (0.91)
	after the cue-utilization activity	3.39 (0.85)
	after instruction and practice	3.66 (0.56)
Knowledge gaps	after problem solving	2.45 (0.87)
	after the cue-utilization activity	2.58 (0.80)
	after instruction and practice	2.33 (0.71)

Further, we analyzed how PF_{cue} students used the worked example during the cue-utilization activity. We compared each solution that students had generated in their groups to the worked example in order to analyze how many differences the students could have found between their own solution and the canonical solution presented in the worked example. Afterwards, we examined how many differences PF_{cue} students actually identified. The results (see Table 4) demonstrate that on average PF_{cue} students were only able to find 25% of their mistakes by comparing their own solution with the solution presented in the worked example.

Table 4: PF_{cue} students' actual mistakes versus identified mistakes

PF_{cue} student group	**Number of actual mistakes** *during problem solving*	**Number of identified mistakes** *during cue-utilization activity*
1	7	3 (43%)
2	4	2 (50%)
3	3	0
4	4	1 (25%)
5	5	2 (40%)
6	4	0
7	3	0
8	4	2 (50%)
9	4	1 (25%)
10	5	0
11	5	1 (20%)
12	4	2 (50%)

The fact that PF_{cue} students had difficulties to identify the differences between their own solution and the canonical solution presented in the worked example is further supported by qualitative analyses of students' work during the cue-utilization activity. These analyses reveal that seven out of the twelve student groups stated that their solution and the worked example were similar. Four out of twelve groups simply describe their own solution as less detailed than the worked example (see Figure 1 for an example). Another recurring pattern in the cue-utilization activity is that some students discuss the study described in the problem-solving task and the potential findings of this study. Specifically, five out of twelve groups thought about circumstances and factors (e.g. age or gender) that may have an impact on whether children show aggressive behavior after playing video games with violent content. Hence, instead of comparing their own solution with the worked example, these groups continued their work of the problem-solving phase. Two groups even just stated their opinions about playing video games with violent content and did not compare their solution to the worked example during the cue-utilization activity.

The analysis of students' work during the cue-utilization activity also showed that students' comparisons between their own solutions and the worked example were often incomplete or not very detailed, which is also illustrated by the example in Figure 1.

	Similarities	Differences
a)	nearly similar content	less detailed (ours)
b)	-	different outcome
c)	same thought, nearly similar content	less detailed (ours)

Figure 1. Example of students' results of the cue-utilization activity (left figure: original solution in German; right figure: English translation).

Discussion

Previous research on Productive Failure (PF) suggests that students' awareness of their failure and knowledge limitations could be a crucial mechanism underlying the effectiveness of PF for student learning (Loibl & Rummel, 2014a; Loibl et al., 2017; Nachtigall et al., 2020). However, students often tend to overestimate their own competence (Kruger & Dunning, 1999) and to use inappropriate cues for monitoring and evaluating their learning (e.g. de Bruin et al., 2017). The same seemingly applies to PF students in certain non-STEM or domain-general learning settings (cf., Nachtigall et al., 2020; Kant et al., 2017; Matlen & Klahr, 2013). To support PF students in recognizing their knowledge limitations while learning social science research methods, we implemented a cue-utilization activity after the problem-solving phase and prior to the instruction phase. Our cue-utilization activity aimed at fostering students' use of diagnostic cues by asking them to compare their self-generated (and often erroneous) solution to a canonical solution presented in a worked example. We hypothesized that this activity would help students to become aware of their knowledge limitations and thus that students in a PF setting with cue-utilization activity would report lower perceived competence (H1) and higher knowledge gaps (H2) prior to instruction than students in a PF condition without cue-utilization activity. As students' awareness of their knowledge limitations is hypothesized to underlie the effectiveness of PF, we further expected that PF_{cue} students would outperform PF students on a knowledge test (H3). However, our findings support neither of these hypotheses.

As our exploratory analyses suggest, a reason for our unexpected findings may relate to students' rather low performance during the cue-utilization activity. Specifically, students had difficulties to identify the differences between their own solution and the canonical solution presented in the worked example. Thus, students in our PF_{cue} condition were either unwilling or unable to critically evaluate their own solutions and to become aware of their previous failure in producing the canonical solution to the problem-solving task. Our exploratory analyses with respect to the development of PF_{cue} students' perceived competence and reported knowledge gaps further suggests that our cue-utilization activity indeed led to a small decline of perceived competence and a small increase of reported knowledge gaps, but only descriptively. Thus, asking students to compare their own and often erroneous solution ideas with a worked example prior to instruction may have potential for fostering students' failure awareness, but probably depends on students' critical and careful evaluation of their own solutions. The lack of students' critique towards their own solutions could relate to students' epistemological beliefs about the social sciences. Pauly (2012) describes that students often associate research within the humanities and social sciences with expressions of individual opinions, feelings, and thoughts and not with systemic investigations of phenomena as in the natural sciences. Thus, the students in our study may have seen no need to critically and systematically evaluate the quality of their solutions. Instead, they might have perceived their solutions as well as the solution presented in the worked example as expressions of individual opinions and thoughts which cannot be systematically evaluated. Another reason could relate to the so-called IKEA effect (Norton et al., 2012). Norton and colleagues (2012) showed in four studies that their participants valued self-made products higher than pre-assembled products. Hence, it is likely that PF_{cue} students in our study ascribed a higher value to their self-generated solutions than to the canonical solution presented in the worked example, whereby they did not reflect accurately on differences between their own solution and the worked example. Further research is needed in order to investigate whether students' epistemological beliefs and/or students' appreciation of their self-generated solutions is related to their low performance during the cue-utilization activity. For this purpose, it might be interesting to conduct post-hoc interviews with the students.

However, as PF_{cue} students did not develop a higher awareness of their knowledge limitations prior to instruction than students in the PF condition without cue-utilization activity, it is not surprising that PF_{cue} students did not outperform PF students on a knowledge test. Instead, this finding is in line with the assumption that students' awareness of their knowledge limitations prior to instruction may be a relevant mechanism underlying the effectiveness of PF. Nevertheless, further research is required in order to both test effective ways for fostering PF students' awareness of their knowledge limitations in a non-STEM learning setting and investigate the role of students' failure awareness prior to instruction for the effectiveness of PF.

Limitations

We conducted our study with real students and real courses which increases the external validity of our investigation and is in line with the *in vivo* experimentation paradigm of the LearnLab at Carnegie Mellon University in Pittsburgh (Koedinger, Aleven, Roll, & Baker, 2009). However, due to the random assignment of whole classes to the experimental conditions, prior differences between PF and PF_{cue} students cannot be excluded.

A further limitation relates to the non-effects of our experimental manipulation. Non-effects revealed by null hypothesis significance tests, such as the F-test, are difficult to interpret. Those tests examine whether a null hypothesis can be rejected and not whether a null hypothesis can be accepted (which is contrary to our hypotheses but suggested by our findings). To address this difficulty, we followed the suggestions by Aberson (2002) and calculated the confidence intervals of the effect sizes (which are reported in the results section above).

One could also see it as a limitation of our study that PF_{cue} students were asked to collaborate while studying the worked example and comparing it to their own solution idea. As PF_{cue} students generated their solution idea in small groups during the initial problem-solving phase – which is in line with one of the PF design principles described by Kapur and Bielaczyc (2012) – we also asked them to collaboratively compare their joint solution idea to the worked example during the cue-utilization activity. However, findings by Retnowati, Ayres, and Sweller (2017) demonstrated that studying a worked example individually leads to higher learning gains than studying it collaboratively. Further research is required to investigate whether this effect also transfers to our cue-utilization activity.

Changes in the Media Landscape in the Wake of COVID-19 as a Catalyst for Data Literacy Development thru Life Routines

Iris Tabak, Ben-Gurion University of the Negev, itabak@bgu.ac.il
Ilana Dubovi, Tel-Aviv University, ilanadubovi@tauex.tau.ac.il

Abstract: Do life circumstances introduce opportunities to learn? COVID-19 created a public need for information on the epidemiological developments of this pandemic, resulting in an upsurge in graphical representations in the media. Using a survey, we examine whether, in the wake of COVID-19, people make greater use of data representations, and whether this relates to their confidence in interpreting these representations. We also evaluate their graph interpretation skills. To understand the role of rudimentary education in this process, we report on participants with 12 or less years of education. We found that people mostly increased their use of graphs, and that this explains an increase in their confidence to interpret graphs. People with stronger skills had a higher increase in graph use. People with weaker skills, also increased, rather than avoided, graph use. Life experiences can prompt change and growth, and the media landscape can play a role in this process.

Introduction

Visual representations of data are prevalent in many facets of everyday life (Wise, 2020): in news media (Allen, 2018; Bao, Cao, Xiong, & Tang, 2020), in lifestyle tracking apps (Byrne, O'Grady, Collier, & O'Hare, 2020), in personal health records (Sharit et al., 2014), and others, making proficiency in interpreting such representations key to civic participation. In fact, data literacy is defined as "the desire and ability to constructively engage in society through and about data" (Bhargava et al., 2015). Consequently, there is increasing interest in the learning sciences in understanding the nature of data literacy and how to cultivate data literacy (Wilkerson & Polman, 2020). One of the hallmarks of research in the learning sciences is drawing on research of everyday reasoning and learning in order to reconceptualize formal education (Hoadley, 2018; Kolodner, 2004) so that it creates usable knowledge, and better equips learners to participate more centrally in various contexts of practice (Lave & Wenger, 1991). We follow this tradition by examining how people reason with data representations in the wake of COVID-19.

The COVID-19 pandemic brought income instability and emotional burden, which as recent reports state, also fueled public interest in COVID-19 data (Bowe, Simmons, & Mattern, 2020). Within a few weeks into the year 2020, COVID-19 became a trending topic worldwide. Production and consumption of COVID-19 data was so high and widespread that the term 'infodemic' (Cuan-Baltazar, Muñoz-Perez, Robledo-Vega, Pérez-Zepeda, & Soto-Vega, 2020) was coined to mark and highlight this striking phenomenon. The high public consumption of COVID-19 data in terms of visualizations, open data repositories, simulations and infographics motivates interest in understanding how the public interpret and effectively use the data (Alberda, Alamalhodaei, & Feigenbaum, 2020).

International standardized tests among both children and adults, public surveys, and educational research reports suggest that data literacy and graph interpretation pose a challenge (Assessment, 2013; Bragdon, Pandiscio, & Speer, 2019; Gonzalez, 2018; Highlights of the U.S. PIAAC Results, 2017; Pérez-Echeverría, Postigo, & Marín, 2018). However, other lines of research highlight the discrepancy that can exist between formal school-like assessments and people's competence and performance in everyday contexts (Lave, 1984; Saxe, 2015; Suad Nasir, 2000). Overall, studies of everyday contexts demonstrate that people are more productive in everyday contexts than what might have been predicted based on formal school-like assessments. COVID-19 has created unique circumstances in which we can gain insights into the ways in which diverse people make use of and interpret graphs.

In this paper, we report on a subset of data from a larger study. The larger study examined a cross-sectional national representative sample of people's information behavior prior to and during COVID-19, and examined how people interpret COVID-related graphs. In the present paper, we focus only on the sub-sample who have up to 12 years of formal schooling. Our goal is to use this sub-sample to better understand the role that rudimentary (K-12) education plays in people's use of data literacy in everyday contexts, and in their trajectories of data literacy development.

Background: Graph interpretation skills

Data literacy builds on the literacies of: numerical literacy; information literacy (including critical thinking about sources); scientific literacy; statistical literacy; computational literacy; and digital literacy. (Bhargava, 2019). In this paper, we focus more specifically on graph comprehension.

Despite the increasing importance of graph interpretation skills, many adults have low graph literacy (Galesic & Garcia-Retamero, 2010; Herrmann, Brumby, & Oreszczyn, 2016). Though people vary in their ability to interpret graphs based on the type of graphical representation, with bar graphs yielding higher performance (Dowding et al., 2017). Full competence in reading graphs is not achieved even by college and university graduates (Nayak et al., 2016; Roth, Bowen, & McGinn, 1999). Facets that are involved in graph comprehension are: understanding representational conventions and understanding the content and context related to the data that is represented (Maltese, Harsh, & Svetina, 2015). One way in which stronger skills are distinguished from weaker skills is in the ability to focus on those aspects of a graph that are most pertinent to the questions that people want to answer by interpreting the graph (Okan, Galesic, & Garcia-Retamero, 2016).

Methods

Participants

500 participants were recruited through a stratified random sample from a panel (N=500). Stratification categories were gender, age, religious status (e.g., ultra-orthodox, secular), and geographic region (e.g., northern Israel, greater Tel Aviv area, etc…). Category sample quotas were established to represent the population demographics of Israel. In this paper, we focus on a sub-sample of N=170 participants who reported that they have up to 12 years of formal education.

Instrument

We developed a 21-question survey to elicit self-reports of information behavior, COVID19 attitudes and behaviors, trust in science, as well as questions assessing graph interpretation skills.

The survey included 1 question collecting demographic information; 4 questions about information behavior addressing: what information sources (e.g., WHO, FaceBook) do participants employ and with what frequency – before and during COVID19, and how reliable they consider the sources; what data representations (e.g., graph, table) they encounter, how frequently, and how confident they are in interpreting the various data representations; 1 question asked about the frequency with which participants employ COVID19 health-protective behaviors (e.g., distancing, wearing a mask) (adapted from: Plohl & Musil, 2020); 14 questions presented different types of graphs with related multiple choice questions that required direct lookup of information in the graph (e.g., which age group in a bar-graph is the age group that does not show symptoms), as well as inferencing (e.g., the table shows the smallest number of infected individuals in the 90 and older age group, yet they are considered a high risk group, how can that be explained based on the data in the table?). This set of questions also included some open-ended questions that required participants to apply the information in the graph to decisions such as whether they would pursue international travel or whether schools should re-open. All but one of the 14 graph interpretation questions were set in the context of COVID19 and were similar to graphs that have appeared in news reports on COVID19. The one graph interpretation question that was not set in a COVID19 context was a question that appeared in the PEW Research Center survey (Kennedy & Hefferon, 2019) and was included in this survey as a way to compare responses in this pool of adult Israeli participants with the Pew's pool of adults in the United States. The last question in the survey was a Likert scale assessing trust in science and scientists (adapted from: Nadelson et al., 2014), and COVID19 risk perceptions (adapted from: Plohl & Musil, 2020).

Face validity was established by having four scholars review the survey. The scholars are experts in public health, mathematics education, and visual representations in cognition and learning with extensive experience in developing and validating research instruments. The survey was refined based on their comments. The survey was further refined by having four volunteers with different levels and fields of education complete the survey.

Procedure

After receiving IRB approval, the survey was distributed online in a cross-sectional study. The survey was implemented in Qualtrics (version September, 2020, Qualtrics, Provo, UT). The survey was distributed through iPanel (https://www.ipanel.co.il/en/), one of the largest polling services in Israel, which adheres to the high-quality research code of the European Society for Opinion and Marketing Research (ESOMAR; Bodas & Peleg, 2020). The survey was distributed during September 2020, during the second wave of COVID19 outbreak in Israel, and at the beginning of a second nation-wide lockdown.

In the present paper, we analyzed data only from those participants who reported that they had up to 12 years of formal education (N=170). We computed descriptive statistics (means, standard deviations, frequencies and percentages) to describe participants tendency to use COVID-19 related data and information sources, as well as their degree of frequency and confidence in using different modes of representation. We used t-tests to examine whether there were significant changes in frequency and confidence prior and during COVID-19. To understand the impact of the participants' characteristics, graphs interpretation skills, frequency of graph use on the confidence of using graph representations following COVID-19 outbreak, we conducted hierarchical regression analysis. Preliminary analyses were conducted to ensure that there were no violations of the assumptions of normality, linearity, and homoscedasticity. In addition, interaction effects between high and low graph interpretation skills were evaluated using repeated measures analysis of variance (ANOVAs). Data was analyzed using SPSS (version 25, IBM Corporation, Armonk, NY).

Findings

Descriptive statistics (Table 1) show that this sub-set of participants were fairly evenly distributed between male and female participants, with about half the participants under 30 years of age, and predominantly of average and below average income.

TABLE 1: Socio-demographic characteristics

Variables	***Participants (n=170)***
	M(SD)
Education (years)	11.7 ± 1.2
	N (%)
Age (years)	
18-22 years	45 (26%)
23-29 years	40 (24%)
30-39 years	24 (14%)

Male	89 (52%)
Income level	
Above average	20 (12%)
Average	45 (26%)
Less than average	106 (62%)

Increase in consulting information sources during COVID-19

Participants' primary sources for COVID-19 information were media and television news, Google search engine, friends and family, WhatsApp messenger and Facebook. Surprisingly, health organization websites such as the WHO and twitter were listed as the venues least used for COVID-19 information. Correspondingly, participants rated the most frequently used sites as more reliable and the least frequently used sites as least reliable. There was a significant increase from before to during COVID-19 in the frequency of use of all information sources (Table 2), with the largest shift in greater use of health organization sites such as the WHO or the Ministry of Health site.

TABLE 2: Information Sources before and during COVID-19 pandemic

	Before COVID-19	During COVID-19	t-test			Before COVID-19	During COVID-19	t-test
Media News and TV	3.9 ± 1.8	4.6 ± 1.7	-6.818***		Physician	2.8 ± 1.2	3.2 ± 1.4	-4.827***
Google search engine	3.7 ± 1.6	4.5 ± 1.4	-7.507***		Workplace	2.7 ± 1.7	3.3 ± 1.9	-5.898***

Increase in reading graphs and in confidence to interpret graphs

We asked participants how often they used different modes of data representation such as tables, simulations, text and graphs, before and during COVID-19, in addition for each mode of representation we asked them to rank their confidence in interpreting the information in that mode. There was an increase in the frequency of use in all modes of representation, and a significant increase in interpretation confidence in all but text and lectures. Graphs showed the highest change before and during COVID-19 in both frequency and confidence (Figure 1).

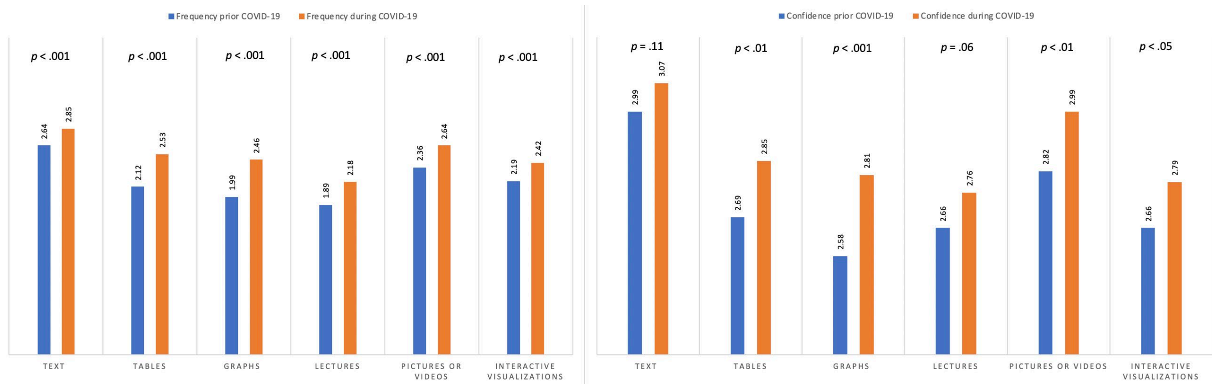

Figure 1. Changes following COVID-19 in frequency and confidence in use of modes of data representation

Graph interpretation skill and its correlates

Graph interpretation questions that involved looking up information in the graph were answered correctly on average by at least half of the respondents. These graphs included both bar graphs and line graphs. One question showed two version of a graph, where the second version includes two additional data points, which have a much higher value than all of the data points in the previous graph. Participants were asked what would happen to the average when these two data points were added to the measurements. 61% of the respondents correctly answered that the average would increase (61±49), demonstrating an understanding of the relationship between individual data points, and represented aggregate information such as average. The most challenging questions for participants, where less than 50% responded correctly, were questions relating to rates of change (36±48), and to changes in numerator or denominator (39±49).

To further understand the impact of participants' characteristics, their graph interpretation skill, frequency of using graphs, on the levels of confidence in using graphs as a result of COVID-19, a hierarchical multiple regression analysis was performed (Table 3). In model 1, contribution of sociodemographic characteristics, only age variable had a significant contribution to the explanation of participants' confidence levels, $F_{(3,\ 162)} = 3.02$, $p < 0.05$, explaining 5% in variance in confidence levels. Incorporation of graphs interpretation skill in and frequency in graph use in model 2 significantly explained additional 37% of the variance in confidence levels, and the entire model 3 explained 42% of the variance in confidence, $F_{(2,\ 160)} = 51.43$, $p < 0.001$.

TABLE 3: Summary of hierarchical regression analysis for variables predicting confidence in using graph representations following COVID-19 outbreak (*N* = 170)

Variable	Model 1	Model 2
	β	*β*
Age	-.19*	-.03
Gender (male)	-.05	.01
Family income level (above average/below average)	.01	.00
Graph interpretation skill		.32***
Frequency in Graph use following COVID-19 outbreak		.48***
R^2	0.05	0.42
F for change in R^2	3.01*	51.43***
ΔR^2	0.05	0.37

*$p < .05$; ***$p < .001$.

In order to better understand the role of graph interpretation skills in the use of graphs during COVID-19, we split the sample based on their total score on the graph interpretation questions, using the median as the splitting point. We conducted a repeated measures ANOVA with time as the within subjects factor using the measures of frequency of graph and of confidence in the ability to interpret graphs, graph skill was the between subjects factor. There were significant differences within each group in both measures across time, and there were significant differences between groups at both time points (Figure 2). There was a significant interaction between time and skill level for frequency $F(1,168)=4.141$, $p<.05$, but not for confidence ($F(1,168)=0.25$, p=.62). There was a significant difference in the rate of change (slope) between the lower graph skill group (0.34) and the high skill group (0.6), $t(84)=2.2$ p=.029.

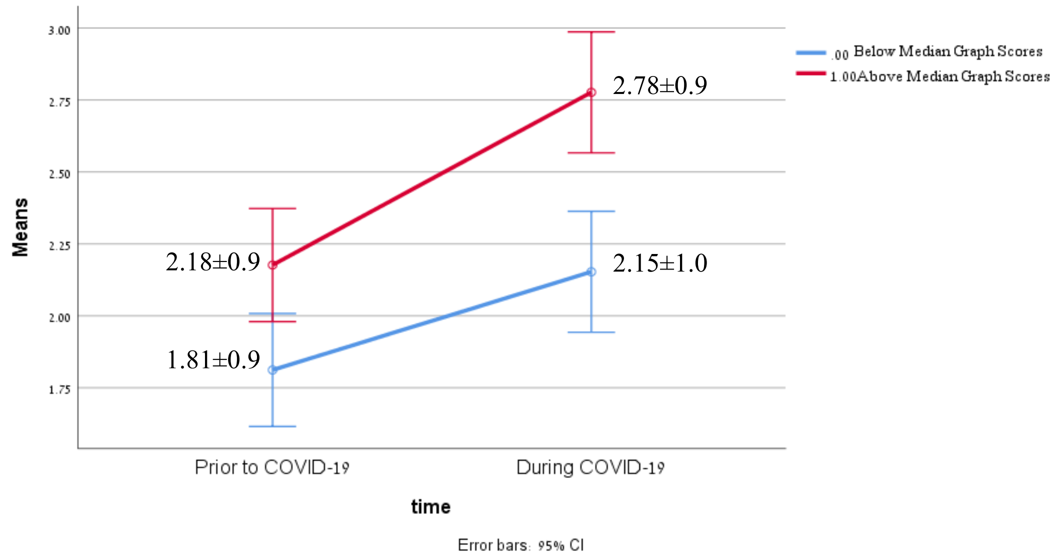

Figure 2. Rate of Change of Frequency of Viewing Graphs Prior to and During COVID-19

Discussion

Our goal in this paper is to connect to research in the learning sciences that considers productive activity in real-world contexts as the prism through which we should understand learning and design in education. Research from this tradition has exposed that performance on highly formalized, decontextualized and abstract assessments can obscure how well people might perform, in context, in response to real-world demands (Lave, 1984; Saxe, 2015; Suad Nasir, 2000). In the present study, we capitalized on the unique circumstances of the COVID-19 pandemic to gain insight into the ways in which the public might interpret and use data representations in a period in which such representations are prevalent in the media, and in which attending to this information carries strong purchase for the course of people's lives. In this paper, we also focus on participants who have up to 12 years of education as a way of reflecting the role of rudimentary education in preparing people for civic participation.

We found that information behavior changed in the wake of COVID-19, and that our participants reported the greatest change in their consumption or use of graphs over other modes of representation. In this discussion, we do not focus on assessing participants' ability to interpret COVID-19-related graphs per se. Instead, we examine what this study teaches us about how information behavior, skills and beliefs interact and influence how we might realize the opportunities to learn that everyday life experiences offer. Our survey includes graph interpretation questions, and our findings reflect prior research (e.g., Galesic & Garcia-Retamero, 2010; Herrmann et al., 2016): at least 50% of the 170 participants were able to correctly respond to most questions. As noted, we will discuss how this knowledge is related to other factors, and how this might affect propensity for change.

As might be expected, proficiency was correlated with confidence in one's ability to interpret graphs. Participants along the full range of proficiency and confidence levels reported statistically significant increases in graph consumption during the pandemic, and in confidence in their ability to interpret graphs. For those with lower confidence in their ability, this is a somewhat surprising result, because people who doubt themselves might tend to avoid graphs. Given the relationship that we found between consuming graphs and feeling confident about interpreting graphs, the fact that even low-confidence participants increased their graph consumption during the pandemic, carries important implications for propensity for change.

Our findings suggest that changes in graph consumption explain confidence, so that increased use of graphs is associated with higher levels of confidence. This finding can advance our understanding of reasoning and change in everyday contexts. Conceivably, experience and practice should lead to increased confidence in one's ability. This is more likely if these experiences are successful. However, in routine life experiences, rather than intentional learning environments, people may not be able to discern whether they were successful, because they may not receive feedback on their performance. In the present context of COVID-19, the media landscape includes a higher number of data representations that are key to understanding and navigating life during the pandemic, and there is increased use or consumption of these graphs, but people do not receive any clear indication as to how well they are interpreting these graphs. Despite this ambiguity, our findings suggest that increased use of graphs led to increased confidence.

However, the process and relationship between use and confidence is complex. When we consider differences between higher and lower performers on the graph interpretation questions, within our sample of individuals with up to 12 years of education, we find that there are significant differences between these groups in terms of graph use and confidence, before and during COVID-19. Moreover, in terms of graph use, the changes during COVID-19 are higher for the higher performing group, but there are no significant differences in the rate of change in confidence between the two groups. We see that prior proficiency with graph interpretation leads to greater changes in using graphs when life circumstances call for consuming this type of information, creating an advantage for those with prior higher proficiency. However, confidence in graph interpretation operates differently, and follows similar patterns of change regardless of prior proficiency. These similarities in rates of change in confidence might be a function of the general lack of feedback on success in everyday contexts, as discussed above.

We would also like to consider some of the limitations of our study and analysis. First, while our goal is to understand how people reason within the media landscape of everyday life, we did not observe people in situ. In order to mitigate this issue, we designed our graph analyses questions to reflect the types of representations that have appeared in the media, and raised questions that reflected some of the public discourse during the COVID-19 pandemic. Another concern might be that people may have reported higher ratings for the COVID-19 period than for the preceding period out of social desirability considerations, sensing that this is the pattern of responses for which the study aims. However, if responses were biased in this way, we would expect this same pattern of bias across all responses, but we found different patterns for different modes of representation, including a decrease in consumption of tables. Similarly, ratings may have been higher for graphs over other modes of representation, given that the survey included graph-interpretation questions. However, the graph interpretation questions appeared only after a sequence of Likert-scale questions concerning information behavior, which we believe reduces the risk of such bias. Finally, we did not have a way to obtain a measure of participants' graph interpretation skills prior to the COVID-19 outbreak, and therefore, cannot ascertain whether people improved their graph interpretation skills. Uncovering how patterns of everyday media use affect learning is an important goal for future research.

Conclusion

The main implications of our research are: (1) that lower graph interpretation ability does not necessarily imply low or no consumption of graphs as part of information behavior; and (2) that people can undergo change and growth as part of life experiences and as a function of the media landscape. However, existing knowledge and skills can affect propensity for change, and therefore we cannot simply rely on people's ability to learn what they need to learn as needs arise over the course of the life span. This study motivates future research into how we can understand and design informal learning in the community.

Abstract: Learners demonstrate difficulties effectively deploying self-regulated learning (SRL) strategies while using game-based learning environments (GBLEs). Features designed to scaffold and support learners' SRL with GBLEs may limit autonomy and impact their performance. However, the effectiveness of limiting autonomy as individual learners engage in SRL over time (i.e., throughout a 90-minute learning session) has been largely unexplored. Therefore, this study examines how learners' prior knowledge and varying levels of autonomy (i.e., full versus partial) moderate the relationship between fixation durations over time on different information representations (i.e., books and research articles, conversations, posters) that are either considered relevant or irrelevant to the pre-test. Undergraduate students (N=82) learned with Crystal Island, a microbiology GBLE. Results identified interaction effects between (1) fixation durations and representations on learning gains and (2) text relevance, type of representation, and relative game time as well as a moderating effect of autonomy.
Keywords: Game-based Learning, Autonomy, Multimedia, Self-regulation, Eye Tracking

Autonomy and SRL during game-based learning

Game-based learning environments (GBLEs) incorporate tasks and game elements while allowing learners full autonomy (i.e., complete control over actions; Bandura, 2001) to enhance learning, motivation, and cognitive engagement (Plass, Homer, Mayer, & Kinzer, 2020; Taub, Sawyer, Smith, Rowe, Azevedo, & Lester, 2020). Because of the open-ended nature of GBLEs, learners must engage in self-regulated learning (SRL) to monitor and adapt their learning strategies to meet goals (Winne & Azevedo, in press). However, as learners typically lack the SRL skills needed to successfully interact with GBLEs (Josephsen, 2017), GBLEs embed scaffolds (e.g., guidance through restricted autonomy) to support learners' use of SRL processes and strategies (Josephsen, 2017).

GBLEs must balance the level of autonomy afforded to learners to simultaneously increase motivation through full autonomy and scaffold learning by restricting autonomy (Dever & Azevedo, 2019; Dever, Azevedo, Cloude, & Wiedbusch, 2020). For example, Crystal Island, a microbiology GBLE, limits autonomy by dictating the order in which learners interact with game elements (e.g., informational text) and forcing learners to engage with all information. However, regardless of the level of autonomy, learners must use SRL strategies to select relevant information from the text, organize the information into a mental model, and integrate their mental models with prior knowledge. As such, it is important to consider how limited autonomy moderates learners' interactions with GBLE elements by capturing process-oriented data as learners monitor and regulate learning processes. This study focuses on how learners' gaze fixations on different information representations (i.e., large paragraphs of text, conversations, posters) within Crystal Island contribute to learning gains, change over time, and are related to representation relevance, learners' autonomy, and prior knowledge.

Capturing SRL via eye-tracking methodology

Eye-tracking methodologies are utilized to capture learners' cognition and SRL strategy use (Azevedo, Taub, & Mudrick, 2018; Catrysse, Gijbels, Donche, De Maeyer, Lesterhuis, & Van den Bossche, 2018; Mayer, 2019). Fixation durations, which are defined as relatively still gaze for at least 250ms, and saccades are regularly used (see Cloude, Dever, Wiedbusch, & Azevedo, 2020) to quantify learners' underlying cognitive processes (e.g., reading; Bolzer, Strijbos, & Fischer, 2015; Catrysse et al., 2018l Cutumisu, Turgeon, Saiyera, Chuong, González Esparaza, MacDonald, & Kokhan, 2019). For example, time fixating on in-game texts indicates when learners are monitoring their understanding of text and capture the total time learners need to process information. These gaze behaviors further indicate learners' ability to accurately and efficiently apply SRL strategies. For example, learners fixating on irrelevant text for a long period of time may indicate the learner has not made an appropriate or efficient content evaluation (i.e., inaccurate metacognitive monitoring). Yet, accurately identifying relevant from irrelevant information is influenced by the multimedia material where accuracy increases when information is represented by multiple modalities (e.g., text and picture versus solely text; Azevedo & Dever, in press; Butcher, 2014; Mayer, 2019, in press). Within this paper, we use eye-tracking data to explore this relationship between information representations and SRL.

Previous research with Crystal Island

Recent studies in Crystal Island utilize eye-tracking data to understand learners' in-game behaviors, deployment of SRL processes, and learning gains (Syal & Nietfeld, 2020; Taub, Mudrick, Azevedo, Millar, Rowe, & Lester, 2017). Dever et al. (2020) compared log-file with eye-tracking data and examined how learners interact with relevant versus irrelevant text in Crystal Island. Their findings suggest that learners' eye-tracking data provides a better indication of how learners interact with information throughout a GBLE compared to log files. Cloude et al. (2020) found moderating relationships between fixations and information gathering actions within Crystal Island where learners with less prior knowledge had a positive relationship between interactions and fixation durations. Taub et al. (2017) used eye-tracking data to examine learners' use of SRL processes where results found that eye-tracking data was essential to capturing the quality of learners' processing through fixation durations. While these studies used eye-tracking data to provide evidence on learners' in-game behaviors and SRL processes associated with heightened knowledge acquisition, they do not address these relationships over time. This current study uses eye-tracking data to assess learning gains in relation to autonomy, prior knowledge, and text representations over time within Crystal Island to examine how these constructs influence learners' SRL strategies while interacting with multimedia materials in a GBLE.

Theoretical frameworks

To examine the relationship between learners' SRL processes, specifically content evaluation, and the cognitive processes required to select and comprehend multimedia material, both Mayer's (2019, in press) CTML and Winne's (2018) COPES models are used to ground this study. CTML is centered around three cognitive processes: (1) selecting relevant visual and auditory information; (2) organizing the selected visual and auditory information into mental models; and (3) integrating mental models together with prior knowledge to construct a cohesive representation of information (Mayer, 2019). These processes are assumed to be linearly structured, limited by learners' cognitive resources, and elicited by learners' active processing of multimedia.

COPES details learners' conditions, operations, evaluations, and standards as they engage in SRL throughout learning (Winne, 2018). Within this paper we examine the conditions, operations, and products that influence learners' interactions with different representations of information. Conditions refer to the types of resources and constraints that are available to a learner through internal (e.g., prior knowledge) or external/environmental (e.g., limited versus full autonomy) factors (Winne, 2018). Conditions can significantly influence learners' deployment of SRL strategies during learning. For example, Taub, Azevedo, Bouchet, and Khosravifar (2014) found that learners with high prior knowledge had a greater number of and duration on SRL strategies than learners with low prior knowledge. Operations are the internal cognitive processes that a learner continuously deploys while learning with a GBLE which, when combined with conditions, results in products, or the new understanding of the content based on information presented in the GBLE (i.e., learning gains).

Current study

Limited research has examined how learners' interactions with information representations change over time as a result of prior knowledge, autonomy, and learners' SRL abilities. The goal of this study is to add to this area by examining learners' fixation durations on relevant versus irrelevant types of representations over time and how learners' prior knowledge and autonomy throughout the environment are related to this interaction by examining three research questions. The first research question focuses on learners' products: To what extent does the proportion of time learners spend on different representations influence learning gains? Supported by CTML, we propose that the greater amount of time learners spent reading information from non-player character (NPC) dialog and posters relative to their total time in game and accounting for the type of representation will increase learning gains. The second research question focuses on learners' operations: How does relative game time, relevance of the text to the pre-test, type of representation, and their interactions account for the variation of fixation durations within and between learners? We propose that (1) the variation in fixation durations within and between learners will be increasingly accounted for as we add these variables within our model, and (2) as relative game time increases, fixation durations across all types of relevant representations will increase at a greater rate than fixation durations on all types of irrelevant representations. The third research question focuses on learners' conditions: How does autonomy and prior knowledge moderate the effects between relative game time, relevance of the text to the pre-test, type of representation, and learners' fixation duration? Supported by previous literature (Dever et al., 2020; Sawyer, Rowe, Azevedo, & Lester, 2018; Taub et al., 2014), we propose that learners with high prior knowledge and limited autonomy will have greater fixation durations on relevant representations over time than learners with lower prior knowledge and full autonomy.

Methods

Participants
Undergraduates (N = 139) from a large North American public university were randomly assigned to either the full, partial, or no agency conditions that varied in the autonomy afforded (see Crystal Island). Only 82 participants ($Range_{age}$: 18-26, M_{age} = 20.1, SD_{age} = 1.69; 68.3% female), split between full (n = 47) and partial (n = 35) agency conditions, were included in our analyses. Participants were removed if they had missing data and measurement errors in eye-tracking calibration (n = 25) or belonged to the no agency condition (n = 32).

Crystal Island: A GBLE for microbiology
Crystal Island, a GBLE set on a remote island, aims to cultivate learners' SRL and scientific reasoning skills by introducing microbiology content through a problem-solving scenario. Learners must identify an unknown disease infecting island residents by reading informational content (e.g., books, research articles, dialogue with NPCs, posters), completing concept matrices corresponding to informational content, filling out a diagnosis worksheet, and scanning food items. Agency conditions were embedded within Crystal Island. Full agency did not restrict participants' interactions with the environment, generalizable to the majority of GBLEs. Partial agency consisted of a predetermined path (i.e., "Golden Path") that restricted the participants' choice of actions to provide learners support and optimize their learning outcomes. No agency required learners to watch a playthrough of Crystal Island. Learners in this condition could not directly interact with any video (e.g., pause, rewind) or game features.

Experimental procedure
At the start of the experimental session, participants signed an informed consent and were calibrated to the eye tracker. Participants then completed a demographic questionnaire, a microbiology content knowledge pre-test, and several self-report measures. Following pre-task measures, participants started the learning session. As participants interacted with Crystal Island, eye-tracking data were collected. Once a correct diagnosis was identified and submitted, participants completed post-task measures including a microbiology post-test similar to the pre-test and self-reports. Participants were then thanked and compensated, receiving $10 an hour (up to $30).

Apparatus
Gaze behavior data were captured using an SMI RED250 eye tracker with 9-point calibration at a sampling rate of 250 samples per second (s). The SMI eye tracker captured fixation durations, saccades, and regressions on pre-identified areas of interest (AOIs) which are boundaries that contain the object on which the participants fixate.

Coding and scoring

Reading
Reading duration and instances were operationalized as learners' fixation duration (i.e., relatively stable eye movements for at least 250ms) on different types of representations using AOIs overlaid on top of each representation. Types of information representations refer to NPCs (informative text, uninformative visual), books and research articles (informative text, no visual), and posters (informative and uninformative text and visual). Books and research articles are combined as both representations contain large paragraphs of text.

Learning gains
Normalized change scores (Marx & Cummings, 2007) are used to identify learning gains, or the differences between pre- and post-test scores, while controlling for the prior knowledge of each participant.

Relevance of representations
Individual representations were evaluated for relevance to the pre-test where if a representation contained information addressed in the pre-test, the representation was classified as relevant (see Table 1). If the representation did not hold any information addressed in the pre-test, the representation was labeled as irrelevant. This classification is based on priming literature (see McNamara, 2005) assuming that participants will identify information as more instructionally relevant based off of the pre-test domain-related questions and is needed for the post-test.

Table 1: Relevance of representations

Representation	Total #	# Relevant Representations
Books & Research Articles	21	12
NPC Dialog	9	3
Posters	10	4

Relative game time

As each participant varied in their total game duration, relative game time was calculated by dividing the time in game participants fixated on content by the participants' total game duration, scaling instances from 0 to 1 so that all participants could be compared. This measure was found to first look at a continuous scaling of time to normalize all participants' time in game, which ranged from 39.7 to 135.8 minutes.

Model building and estimation

Our model examines how fixation duration, the outcome variable, was related to several observation- and individual-level variables (see Table 2). Several leveraging outliers ($N = 72$), i.e., data that falls approximately 1.5 interquartile ranges below or above the first and third quartile of data respectively, from the observations were removed from analyses. Fixation duration values were transformed through natural logs to normalize the data (skew and kurtosis < |2|) and reduce heteroscedasticity. As such, geometric means for fixation durations are interpreted within results. Two-level multilevel linear growth models analyzed our hierarchically structured data with observations (i.e., level one, $N = 4274$) nested within individual learners (i.e., level two, $N = 82$) where each learner had approximately 52 observations (Range: 25-75). Observation-level variables included relative game as a latent time variable with a random slope in all growth models. To interpret model intercepts, relative game time values were forced to zero to exemplify learners' first interactions with representations as learners cannot fixate on a representation when they first enter the game. Pre-test relevancy (irrelevant versus relevant) and type of representation (i.e., NPC, books and research articles, posters) were added as fixed effect observation-level variables. Individual-level variables included pre-test scores and conditions.

Table 2: Definitions of variables included in the models.

Level	Variable	Definition	Effects
Observation-Level (Level 1)	Relative Game Time	Proportion of time learners initiate an action.	Random
	Representation	Book or Research Article, NPC, Poster	Fixed
	Relevance	Representation contains information related to a question on the pre-test (1). Representation does not contain information related to a question on the pre-test (0).	Fixed
Individual-Level (Level 2)	Condition	Full Autonomy (1); Restricted Autonomy (0).	Fixed
	Prior Knowledge	Raw scores on the domain knowledge pre-test quiz.	Fixed

Five models were calculated using maximum likelihood estimation within R (R Core Team, 2019) utilizing packages 'lme4' (Bates, Maechler, Bolker, & Walker, 2015), 'jtools' (Long, 2020), and 'emmeans'

(Lenth, 2020) for model building and analysis. The unconditional means model was estimated first. Based on this model, the intraclass correlation coefficient was 0.05, suggesting that about 5% of the variation in fixation duration on representations within Crystal Island is between learners and about 95% is within learners. There was a statistically significant variation between learners (t(82.64) = 75.14, $p < .01$). Thus, it is reasonable to proceed with multilevel linear growth models. The next four models were built with: (1) an unconditional growth model; (2) level one predictors and their interactions; (3) predictors from (2) and level two predictors; and (4) predictors from (3) and cross-level interactions. Tests of model fit were calculated using maximum likelihood estimates.

Model 4: $Y_{ti} = \pi_{0i} + \pi_{1i}(RelativeGameTime) + \pi_{2i}(TypeofRepresentation) + \pi_{2i}(PretestRelevance)$
$+\pi_{3i}(RelativeGameTime^{*}TypeofRepresentation$
$+ \pi_{4i}(RelativeGameTime^{*}PretestRelevance)$
$+ \pi_{5i}(RelativeGameTime^{*}TypeofRepresentation^{*}PretestRelevance) + e_{ti}$

$\pi_0 = \beta_{00} + r_0$
$\pi_1 = \beta_{10}$
$\pi_2 = \beta_{20}$
$\pi_3 = \beta_{00} + \beta_{01}(Condition) + \beta_{02}(PriorKnowledge)$
$\pi_4 = \beta_{10}$
$\pi_5 = \beta_{20}$

Results

Research question 1: To what extent does the proportion of time learners spend on different representations influence learning gains?

A multiple linear regression was run and, while the overall model was not significant ($p > .05$), there was a significant interaction effect for proportion of time fixating on NPCs (t(485) = 8.99, $p < .05$) where as proportion of time on NPCs increased by one unit, normalized change scores increased by 0.48 points. As the proportion of time fixating on books and research articles increased by one unit, normalized change scores increased by approximately 1.28 points compared to the proportion of time fixating on NPCs (t(485) = 2.81, $p < .01$). Proportion of time on posters did not significantly relate to learning gains. In sum, the proportion of time spent on NPCs as well as books and research articles were positively related to normalized change scores.

Research question 2: How does relative game time, relevance of the text to the pretest, type of representation, and their interactions account for the variation of fixation durations within and between learners?

To answer this question, we utilize Models 1 and 2. Model 1, the unconditional growth model, includes time as a level-1 predictor of learners fixation duration. The average fixation duration at participants' initial interaction with text is approximately 31.19s (SE = 0.06) and decreases by approximately 67% (i.e., 20.81s; SE = 0.11) for every unit increase in relative game time. This model (BIC = 14379, D = 14329) is significantly better in terms of fit than the unconditional means model (BIC = 14582, D = 14557) wherein adding time, the model explains approximately 11% of individual-level variance in fixation duration ($\chi 2(3)$ = 227.41, $p < .01$). Model 2 (BIC = 12623, D = 12506) examined the extent to which level 1 variables contribute to variation in learners' fixation durations. This model is a significantly better fit than the unconditional growth model ($\chi 2(8)$ = 1822.8, $p < .01$). Holding all other variables constant, the average fixation duration is 104.58s (SE = 1.08, t(301.39) = 60.69, $p < .01$). There was a main effect for relative game time where, holding all variables constant, fixation durations decreased 89% (i.e., 93.08s) for every unit increase in relative game time (SE = 16.15; t(653.86) = -13.36, $p < .01$). There was a main effect where, when text was relevant, fixation durations were greater than those on irrelevant text by approximately 25.9% (i.e., 27.04s; SE = 1.96; t(4186.66) = 3.37, $p < .01$). There were significant differences between the type of representation and their effect on fixation durations. In comparison to book and research article observations and holding all other variables constant, fixation durations are lower on both NPCs and posters by approximately 85.6% (i.e., 89.55s; SE = 6.49; t(4200.02) = -26.8, $p < .01$) and 91.5% (i.e., 95.65s; SE = 9.01; t(4210.62) = -28.31, $p < .01$) respectively.

Holding all variables constant, there were significant two-way interactions between relative game time, NPCs (t(4211.68) = 11.85, $p < .01$), and posters (t(4209.54) = 8.86, $p < .01$) compared to book and research articles. Books and research articles (by 92.6% or 96.89s; SE = 14.45; see Figure 1) decreased at a greater rate over time than posters (by 44.4% or 46.43s; SE = 7.68). NPCs did not have a significant decrease in fixation durations over time. There was a significant interaction effect for pre-test relevancy and relative game time where fixation durations on relevant text were lower over time than fixation durations on irrelevant text by approximately

56.4% (i.e., 58.98s; SE = 11.63; $t(4182.43) = -4.65$, $p < .01$). When examining a three-way interaction and controlling for all observation-level variables, fixation durations on relevant posters (SE = 9.75; $t(4180.03) = 2.65$, $p < .05$) and NPCs (SE = 40.01; $t(4176.82) = 6.70$, $p < .01$) increased over time by 53.7% (i.e., 56.19s) and 206% (i.e., 215.94s) respectively compared to fixations on books and research articles. As relative game time increased, fixations decreased on relevant books and research articles by 95.1% (i.e., 99.50s; SE = 17.85) and posters by 54.3% (i.e., 56.83s; SE = 10.73). Over time, fixation durations decreased on irrelevant books and research articles by 88.9% (i.e., 92.95s; SE = 16.67) and posters by 32.3% (i.e., 33.78s; SE = 6.46).

In sum, fixation durations generally decreased at a greater rate over time for representations that were relevant to the pre-test than irrelevant. However, there were only significant interaction effects on fixation durations between books and research articles (regardless of relevancy to the pre-test) and posters relevant to the pre-test where fixation durations decreased over time.

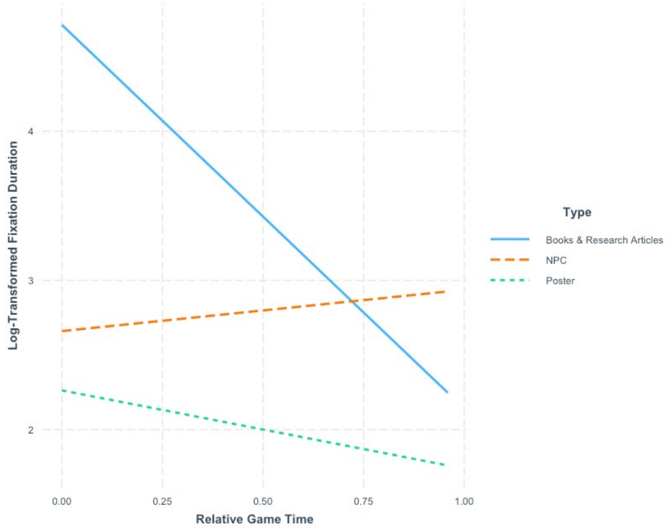

Figure 1. Interaction between relative game time, fixation durations, and type of representation.

Research question 3: How does autonomy and prior knowledge moderate the effects between relative game time, relevance of the text to the pre-test, type of representation, and learners' fixation duration?

Preliminary analysis on condition and learning gains using a t-test confirmed participants with partial agency ($M = 0.45$, $SD = 0.27$) had significantly greater learning gains than participants within the full agency condition ($M = 0.32$, $SD = 0.26$; $t(71.6) = 2.18$; $p < .05$). Because of this significant preliminary finding, Model 3 (BIC = 12640, $D = 12506$) added prior knowledge and condition as variables but these variables were not significant ($ps > .01$). Model 4 (BIC = 12608, $D = 12466$) examined the moderating effects of condition on the relationship between the type of representation and fixation duration. This model was a significantly better fit than Model 2 ($\chi 2(3) = 40.43$, $p < .01$), explaining approximately 44% of individual-level variance in fixation duration. Prior knowledge was initially included but removed due to non-significance. While there was no moderating effect ($ps > .01$) of condition on the relationship between NPCs and fixation durations over time, there was a three-way cross-level interaction effect where learners who were in the full agency condition had greater fixation durations on books and research articles over time compared to learners in the partial agency condition ($t(169.3) = 3.89$, $p < .01$). For every unit increase in relative game time, fixation durations on books and research articles increased by 97.4% (i.e., 101.84s; SE = 18.87) for learners with full autonomy than those with partial autonomy. For every unit increase in relative game time, fixation durations on posters decreased by 30.2% (i.e., 31.62s; SE = 5.86) for learners with full autonomy compared to those with partial autonomy. In sum, learners with more control during gameplay had increasingly greater fixation durations on books and research articles over time and lower fixation durations on posters compared to learners with restricted control, regardless of prior knowledge.

Discussion and future directions

The goal of this paper was to examine how learners' fixation durations on relevant and irrelevant types of representations changed over time and how prior knowledge and autonomy moderated this relationship. The first research question examined how learners' products were related to the proportion of time fixating on different types of representations. Results partially support our hypothesis where the proportion of time fixating on NPCs and books and research articles were positively related to learning gains, but there was no relationship between posters and learning gains. This is not in complete alignment with CTML (Mayer, 2019, in press) where NPCs have text, pictures, and audio, and posters have both text and pictures, but books and research articles only contain large blocks of text. Findings may be attributed to the breadth of knowledge contained within books and research articles where posters do not explain relationships between terms or constructs related to microbiology.

Results for the second research question did not confirm our hypothesis where, as relative game time increased, fixation durations tended to decrease. Interestingly, results showed an interaction between text and relevancy where fixation durations tended to decrease at a greater rate over time for posters and books and research articles that were relevant than texts that were irrelevant. This may be due to the presence of other instructional activities within Crystal Island such as completing concept matrices, filling out the worksheet, and scanning items (Azevedo et al., 2018). However, this result emphasizes learners' inability to consistently and accurately use SRL strategies, such as content evaluations, throughout the game (Taub et al., 2020).

The third research question examined how findings in research question two are affected by autonomy. Results did not support our hypothesis and contradicted prior works where learners with full autonomy had increasingly greater fixation durations on books and research articles over time and lower fixation durations on posters compared to learners with limited autonomy, regardless of prior knowledge (McCardle & Hadwin, 2015; Winne, 2018). Previous work has emphasized the relationship between autonomy and learning gains (Dever et al., 2020). Traditionally, limited autonomy is associated with greater learning gains (Dever & Azevedo, 2019; Dever et al., 2020; Sawyer et al., 2018). Between the first and third research question results, learners with full autonomy had greater fixation durations on books and research articles over time which is further associated with greater learning gains. When accounting for preliminary findings on autonomy and learning gains in the third research question, results from this study suggest that learners with full autonomy were not able to employ efficient or accurate SRL strategies while reading books and research articles whereas learners supported in their actions throughout gameplay had significantly less time interacting with information, but efficiently employed SRL strategies to achieve greater learning gains.

Findings from this current study partially validate the relationship between COPES and CTML where we find that learners' conditions and operations are directly related to their products, especially as we explore the role of different types of representations of information within GBLEs. This study serves as a baseline for future studies to further examine the relationship between COPES, autonomy, and information representations over time within GBLEs. Future studies should incorporate searching, monitoring, assembling, rehearsing, and translating processes into the COPES and CTML model over time within GBLEs to better understand how SRL strategies are used by learners over time (Azevedo & Dever, in press). From the results, we identify the need for adaptive GBLEs depending on learners' eye-tracking behaviors as they read information over time and between different types of representations, especially as we see mixed results compared to previous studies about the role of autonomy as a scaffold for acquiring information. Using adaptive GBLEs from learners' gaze behaviors has the potential to better support learners in navigating the environment, selecting relevant instructional text, and integrating this information to increase learning outcomes while supporting self-regulated learning.

Abstract: Scientists use epistemic criteria to evaluate products of scientific inquiry, such as models. Engaging students with epistemic considerations as part of scientific practice is a growing focus of science education. Recent research has shown that students are able to identify and describe criteria for good scientific models. However, we know little about how students reason about and justify why specific criteria are important and which criteria are more important. In this study we explore these questions using data from interviews with 5th grade students. Interviews were conducted after a five-week model-based inquiry intervention and focused on students' reasoning about a set of criteria for good models developed by the class. Our findings illustrate the array of justifications provided regarding the importance of different criteria in their own right and relative to other criteria. We discuss implications for supporting students' use and evaluation of epistemic criteria in scientific practice.

Introduction

Recent reforms in the US have emphasized engagement with the practices of science and engineering as central to scientific literacy (NGSS Lead States, 2013). Competent engagement in practices involves both "doing" the practice and understanding what it means to do the practice (e.g., constructing models or explanations) (Barzilai & Chinn, 2018). Epistemic competence includes engaging in reliable cognitive processes to achieve epistemic aims that meet valued epistemic criteria (Barzilai & Chinn, 2018). These epistemic criteria are, "…the standards scientists use to evaluate the validity and accuracy of scientific products such as models, arguments, and evidence" (Pluta et al., 2011, p. 1). Examples of epistemic criteria for good scientific models or explanations include: models or explanations should fit the evidence, be conceptually coherent, fit with other established theories, and be parsimonious (Kuhn, 1977; Longino, 2002). These criteria become the guidelines for how to create, refine, and evaluate models. For example, models that fit with evidence have greater validity than models that are unsupported. Scientific communities have developed epistemic criteria that are shared and justified in terms of why they are important. Scientists may prioritize some criteria over others in pursuit of an aim. For example, a model's fit with evidence may be viewed as more critical than how parsimonious it is. Prioritization of epistemic criteria changes over time and may vary by discipline or even area of research. In general, however, criteria use is a core aspect of scientific practice across disciplines (Longino, 2002).

In this study we focus specifically on the practice of scientific modeling and the use of epistemic criteria to evaluate models. Giere (2004) defined models as, "…idealizations that scientists use to represent aspects of the world for specified purposes" (p. 742). Examples include the Copernican and Ptolemaic models of the solar system and Bohr's plum-pudding model of atoms (Frigg et al., 2020). Models are useful because they enable scientists to explain and predict natural phenomena. The process of building, testing, and refining models occurs within a community of practice in which scientists critique each other's ideas. Oreskes (2019) argued that through community argumentation, justification, and critique scientists can revise and build better epistemic products. As noted above, a key piece of the social construction of knowledge is deploying the criteria developed and accepted by the scientific community to critique and evaluate the epistemic products created by its members.

Given the centrality of epistemic criteria in scientific practice, we have argued that it is important to engage students in the development and use of epistemic criteria in science learning (Pluta et al., 2011). Developing, using, and justifying epistemic criteria provides two core benefits. First, it helps students develop a better understanding of scientific knowledge production and how scientists evaluate epistemic products (models, arguments, evidence) and decide between competing claims/models. Such understandings are crucial for a scientific literacy that espouses an informed trust in science. Second, similarly to how they function in the scientific community, epistemic criteria can be used by communities of learners to evaluate their own epistemic products. In this sense criteria can function as scaffolds to guide the production and evaluation of models. Given these arguments for the benefit of epistemic criteria use, the obvious question is whether students are able to productively engage with the development and use of such criteria.

Research suggests that students can do this. Pluta et al., (2011) found that seventh graders were able to generate a wide variety of epistemic criteria for good models and that the criteria align with those proposed by scientists. Av-Shalom et al., (2018) found that seventh graders grew in their ability to recognize and use fit with evidence as an epistemic criterion, which is a central criterion in modeling. However, research that investigates younger students' epistemic considerations when evaluating claims and evidence is sparse (Sandoval et al., 2014), and much of the current research has focused on students' description and use of shared criteria (e.g., Ryu & Sandoval, 2012). We know little about how students justify why these criteria matter, which criteria matter in different situations, and whether some matter more than others. When students talk about such justifications of criteria, they are engaged in *meta-epistemic discourse*, which involves explicit discussions about these criteria and the reasons why they matter (Chinn et al., 2020). Our study therefore focused on the kinds of justifications students provided for why specific criteria are important, and how multiple criteria relate to each other and are prioritized as a set (i.e., ordering within the set). Our research questions were as follows:

1. What criteria do fifth grade students develop for model quality?
2. How do students prioritize criteria?
3. What justifications do students give for why individual criteria are important?
4. What justifications do students provide for reasoning about criteria sets and order within a set?

Method

Context and participants

The study was conducted in a fifth-grade classroom during a five-week model-based inquiry unit with 50 students. During the unit, students reviewed evidence in the form of reports and simulations to develop a model that explained why fish were dying in a local pond (a eutrophication phenomenon). Students made models in a new modeling software called MEME (Model and Evidence Mapping Environment) that enabled them to create components and link them with arrows (mechanisms) to provide a causal account. Students could link evidence (the reports and simulations) to the various elements of the model.

The unit began with an activity in which students developed a shared class list of criteria for good models. To develop the class criteria list, students reviewed a series of model pairs, determining which model in each pair they believed to be the better model and why. Based on these evaluations, students individually made a list of the most important criteria for good models and ranked the order of importance. Through a class discussion the teachers drew on students' suggestions for criteria to develop a class list of five shared and agreed-upon criteria for good models. The class criteria list was revised once throughout the unit. Thus, students had opportunities to use the criteria as they developed and revised their models as well as when they critiqued peer models.

The unit was taught in a public charter school in the Northeast of the United States. The school performs above average on standardized state tests on Mathematics, Language Arts and Science. The demographics of the school were 60% White, 22% Asian, 9% African American, 7% Latinx, and 2% other; 5% of students were eligible for free and reduced lunch.

Data collection and analysis

The data for this study are from interviews that were conucted at the end of the intervention. Sixteen students were interviewed in dyads. The interview consisted of a series of questions to assess students' conceptions of criteria for good models, including criteria importance, order, and justifications. In the interview, students were briefly shown their class's final criteria list and then were given the individual criteria and asked to order the criteria from most to least important. As students were ordering the criteria list, they had the option to add any additional criteria they felt were not covered by the class list. Students were then asked to provide justifications by explaining why they chose the order that they did, beginning from the most important and working their way down to the least important. They were also asked if any criterion was way less or way more important than the others or if they were all similar in importance.

The interviews were videotaped, audio recorded, and later transcribed. The transcripts were then reviewed to identify instances in which students provided reasons about why criteria are important, or why one criterion was more important than another. Through constant comparison (Glaser, 1965), these statements were categorized based on the kinds of justifications they presented. We discuss these categories in the next section.

Results

Research Question 1: What criteria do fifth grade students develop for model quality?

As noted above, students generated a criteria list early in the intervention and then revised it later. The final list is shown in Figure 1.

1. Be organized, clear, and explain what is happening
2. Include relevant evidence
3. Include evidence to support both components and mechanisms
4. Include thorough explanations of the evidence (should completely explain what the evidence shows or why it is relevant
5. Not have extra or irrelevant components, mechanisms, or evidence (all should help answer the question)

Fig 1. Class Criteria List

It is important to note that while there are five criteria in the final list, some of them include multiple ideas that arguably could have been separated into separate criterion. For example, the criteria "*be organized, clear, and explain what is happening"* includes three separate ideas or propositions: be organized, be clear, and explain what is happening. This proved to be important for our analyses because during the interviews students sometimes referred to one, two, or all of the propositions within a criterion, and dyads differed in how they treated criteria in this sense. For example, some dyads referred to particular criteria as a whole (e.g., "*be organized, clear and explain what is happening"* treated as a single criterion), whereas other dyads referred to only one proposition within the criterion (e.g., "*be organized* or *explain what is happening"*). There was also redundancy, as some ideas appeared in multiple criteria. For example, the notion of evidence appeared, in some form, in four out of the five criteria: evidence needs to be relevant (2), it needs to support both components and mechanisms (3), it should be thoroughly explained (4), and there should not be extra evidence (5).

In a prior study of individual seventh graders' development of lists of criteria, Pluta et al., (2011) classified students' criteria into five broad categories: (a) criteria that articulated the goals of models, such as explanation; (b) criteria related to evidence fit, such as quality and quantity of support; (c) criteria that specified constituent parts that needed to be present, such as diagrams; (d) criteria related to communicating the model clearly, such as being clear and organized; and (e) criteria related to other epistemic features such as accuracy. The criteria in the 5th grade class list in this study fall into four of the five categories: (a) goals of models (explain what is happening); (b) evidential criteria (include evidence to support both components and mechanisms); (c) criteria that specified constituent parts that needed to be present (not have extra or irrelevant components, mechanisms, or evidence); and (d) communicative elements (be organized and clear). There were no criteria related to the fifth category, epistemic features, from Pluta et al., (2011).

Research Question 2: How do students prioritize criteria?

In the interviews, students were asked to prioritize criteria from most to least important. Table 1 shows the class criteria list and how many dyads placed each criterion in the first to fifth location on the list. In our analysis, the placement of criteria was given a point value: A criterion in first place was awarded five points, a criterion in second place was awarded four points, and so on. These points were added to yield a "total points" score (shown in the final column) to give a sense of overall criteria prioritization among the dyads.

Table 1: Ranking of criteria and corresponding point value

Criteria	**1st**	**2nd**	**3rd**	**4th**	**5th**	**Total Points**
Include evidence to support both components and mechanisms	3	2	2	1	0	**31**
Be organized, clear, and explain what is happening	3	1	2	2	0	**29**
Include thorough explanations of the evidence (should completely explain what the evidence shows or why it is relevant)	1	2	2	1	2	**23**
Include relevant evidence	0	3	2	0	3	**21**
Not have extra or irrelevant components, mechanisms, or evidence (all should help answer the question)	1	0	0	3	4	**15**

Criteria prioritization reveals a few general trends. The criteria "*be organized, clear and explain what is happening*" and "*include evidence to support both components and mechanisms*" were ranked the highest. The criterion "*not have extra or irrelevant components, mechanisms, or evidence (all should help answer the question)*" was ranked lowest. The criterion "*include thorough explanations of the evidence (should completely explain what the evidence shows or why it is relevant)*" and "*include relevant evidence*" varied in placement across dyads with the largest spread throughout. However, these trends were weak as there was variation in placement across dyads. More information is given in the next section about why this variation may have occurred, as we analyze the justifications students gave for why each criterion was important.

Research Question 3: What justifications do students give for why individual criteria are important?

Students gave a variety of reasons for why each criterion was important. Table 2 shows the class criteria and the justifications students gave for why each criterion is important. The frequency counts are given after each justification type. For example, three dyads said that the first criterion ("*include evidence to support both components and mechanisms*") is important because it makes the model believable. The frequency counts vary because in some cases students gave only one reason in support of a criterion, whereas in other cases they gave several reasons (this varied across criteria and dyads). Also, sometimes one student spoke for the dyad, whereas at other times both students spoke and either gave different justifications or elaborated upon each other's ideas. Elaborations of the same justification by both students within a dyad were counted as one instance. Elaborations that focused on a different aspect of a criterion or a different justification were counted as two separate responses. This resulted in an unequal number of justifications per criterion.

Table 2: Justifications for why individual criteria are important

Criteria	Justification Types (Frequency counts)
Include evidence to support both components and mechanisms	• Evidence makes the model believable, true or correct (3) • Evidence shows why something is happening, or it shows the thinking behind the model (2) • Evidence should support all components and mechanisms; all parts of the model (2)
Be organized, clear, and explain what is happening	• When a model is clear and organized it is understandable or readable (5) • The model will show what it's supposed to show (1) • People will be able to think how you think (1)
Include relevant evidence	• Relevant evidence means the parts of the model, idea and purpose are understandable (2) • Relevant evidence explains the model (1) • Without relevant evidence, no one will believe you (1)
Include thorough explanations of the evidence (should completely explain what the evidence shows or why it is relevant)	• Explaining the evidence is needed so people know what the model is showing, the main idea, why something happens (4) • Explanations show how the evidence supports the model (3) • Without explanations and evidence there is no model (1) • Evidence makes the model true- evidence proves the point (1)
Not have extra or irrelevant components, mechanisms, or evidence (all should help answer the question)	• Have to have real information (1) • Focus on what we need first; not having everything you need is worse than having everything you need plus extras (1) • Extra/irrelevant pieces aren't good- makes the model unfocused and off topic (1)

The reasons students gave for the importance of each criteria were varied. Due to space constraints, the justifications for two criteria will be more fully discussed here. The first criterion ("*include evidence to support both components and mechanisms*") was selected because it was the highest ranked and because evidence fit is a centrally important epistemic consideration. Students valued evidence because they viewed it as making the model accurate. Students referred to accuracy through the terms, "believable," "true," or "correct." Students also valued evidence because they viewed it as showing why something is happening. This implies that students understood the role of evidence in making the model valid, accurate, and complete. Finally, students specified that evidence must support all parts of the model, not only one piece. This shows that students understood that models are not a unitary entity but have constituents that all need to be supported individually. Their justifications for this criterion show that students valued fit with evidence in general because it confers accuracy and validity, as well as in more nuanced ways—in terms of the need to specifically support each and every part of the model.

We discuss the second criterion ("*be organized, clear, and explain what is happening"*) because out of all the justification types, the idea of understandability was stated most frequently and was applied to justify this criterion. Five dyads explained that this criterion was important because a model that was clear and organized would be understandable. Students also said that this criterion was important because if a model is clear and organized, then it will achieve its purpose (show what it is supposed to show), and the audience will be able to follow your reasoning (think how you think). This shows an awareness of the communicative role of model representations and the importance of clearly representing one's ideas. These justifications also point to students' understanding that models have an epistemic purpose or aim that they need to achieve.

We wish to note that students cited understandability as a justification for four out of five criteria, which shows it was not only a popular justification for the criterion "*be organized, clear and explain what is happening"*; it was a popular justification for criteria in general. Students said that models that are organized and clear, include relevant evidence, show how evidence supports the model, and have fewer (and only needed) parts, will be understandable. Although the justification of understandability was given for different reasons, the frequency of this justification type shows that students privileged understandability as an important justification for criteria for good models but also used this justification in different ways (i.e., had different notions of what understanbilty means in relation to models).

Another interesting pattern was the variation in justifications students gave for why evidence is important. (These justifications spanned the four criteria that mentioned evidence.) Out of the 29 total justifications given, 20 pertained to evidence. Some dyads argued that evidence is important because it makes the model accurate (i.e., evidence makes the model true, correct, or believable). This supports the previous point that students are relating evidentiary support to model accuracy. Some dyads related evidence to understandability claiming that relevant evidence means that parts of the model (i.e., components and mechanisms) are understandable, whereas other dyads reasoned that relevant evidence makes the idea or purpose of the model understandable. Finally, some dyads thought that without evidence and explanations, there would be no model. These results show that students understood the importance of evidence in multiple distinct ways.

Research Question 4: What justifications do students provide for reasoning about criteria sets and order within a set?

Students also reasoned about criteria as a set and the order within the set. Students discussed criteria as a set by giving reasons for why certain criteria were more important than others by discussing criteria in relation to each other. This section extends the prior results by focusing on connections across and between criteria.

Table 2: Justifications about criteria sets and order within a set

Justification	**Example**
Encompass other criteria. A criterion is more important because it encompasses others.	This is first because it includes all the other criteria mixed into one.
Specificity. A criterion is more important because it is more specific.	These two are about the same but this one [irrelevant pieces] is more specific...
Essential to the model. A criterion is more important because it is essential to even having a model.	Without explanations and evidence there is no model.
Redundancy. A criterion is less important than others because it is redundant.	One is opposite of the other so they're kind of saying the same thing.
Already known. A criterion is less important because it is already known.	We put this one last because this is something you already know.

The first justification, encompass other criteria, was used to explain why one criterion was more important because it encompassed others. This is shown in the following excerpt from a transcript of Ivy and Arya explaining why they chose their first criterion "*be organized, clear, and explain what's happening*". Note that throughout this section, the descriptions in brackets clarify what the speaker was referring to:

Ivy: Umm, so we chose the order because like, because like you first want to make sure it's organized and clear 'cause like... if you... if that was like the last thing you would do, then um... you would like... then it wouldn't be that clear because then maybe like organizing clearly first is like the uh the hard thing to do, so you want to get it done first. Yeah.

Arya: To add on to what she said, if you have a model that's really messy, if somebody's trying to get a conclusion out of it, they're not going to be able to understand what's happening because they're going to get confused, and it's like more important for people to understand your model and for you to explain it thoroughly as if they don't know like what's happening.

Ivy: Yeah, and like these [all criteria apart from the first one] would just be extra checking, organized and clear.

Ivy and Arya explained that the first criterion ("*be organized, clear, and explain what's happening"*) is the most important because the model needs to be understandable. If the model is messy it will be confusing, and the reader will not understand what is happening. Therefore, the dyad concluded, all other criteria are basically encompassed by (or subordinate to) this first criterion.

Other dyads referred to the idea of some criteria being encompassed by others, but in a slightly different way, by claiming that one criterion was entailed by another. For example, Geona and Deborah argued that the fifth criterion ("*not have extra or irrelevant components, mechanisms, or evidence [all should help answer the question]"*) implies that relevant components and evidence are included and therefore entails the third criterion ("*include relevant evidence"*).

Deborah: It ["*not have extra or irrelevant components, mechanisms, or evidence (all help answer the question*)"] included already like relevant evidence.

Geona: Yeah like "*extra and irrelevant components*" it shouldn't have that so that means it should include relevant evidence.

The second justification privileged specificity; that is, more specific criteria are better. This rationale was given by John and Miguel for why the criterion "*not have extra or irrelevant components, mechanisms, or evidence (all should help answer the question)"* was ranked higher than the criterion "*include relevant evidence."*

John: "*Not have extra or irrelevant components, mechanisms, or evidence."* I still think it's the same as this "*include relevant evidence"*. It's just saying don't have extra irrelevant evidence so it's basically the same. Don't have uh, have relevant evidence and then mechanism and components, that's a little more detailed than this one so we put this one ahead.

John and Miguel reasoned that these two criteria are basically the same, but the prior criterion was more specific and detailed and was therefore ranked higher.

The third justification type was that some criteria are important because what they specify is essential to models and modeling. This was shown in the justifications given by two dyads. The first dyad, Geona and Deborah, stated that the criterion "*include thorough explanations of the evidence (should completely explain what the evidence shows or why it is relevant)"* was the most important because if a model doesn't have explanations and evidence, then there is no model:

Deborah: Umm because here the most important thing for a model is that it shows ummm it needs to show explanations cause without like explanations and evidence there's basically no model.

The students perceived explanations and evidence as being so integral to the model that it is not possible for a model to exist without them.

Another dyad, Patrick and Grant, explained that the criterion "*be organized, clear, and explain what is happening"* is the most important because if it is not organized the audience will not be able to read and understand it, rendering it pointless:

Patrick: Because organize, clear, and explain what is happening is the most important because if it's not organized then other people won't be able to read it so basically there's no point in doing it if it's not organized or clear.

This implies that clearly communicating ideas through the model is of paramount importance. If the audience are not able to read the model, the ideas within it will not be communicated or understood, therefore the purpose for making the model has not been attained.

The fourth justification type ranked some criteria lower because they were deemed redundant. By redundant, we mean that other criteria were more important and covered the most important standards for good models. Therefore, the criteria that are classified as redundant are a part of the set, but they are not as significant as others. For example, Laila and Olympia explained that the criterion "*include relevant evidence*" is the least important because a lot of the other criteria already show that evidence is important:

Laila:	Umm... we put this one last because we already have a lot of these that show that evidence is really important to have in a model and that it needs to answer the question so that it makes sense. So, including relevant evidence is sort of just like… including relevant evidence means that you need to include good and pretty good evidence, but I think these are more important because you need to have mechanisms and components and umm... you need to make sure your evidence connects with the question and you have to be organized and clear and explain what's happening.

Laila explained why the criterion "*include relevant evidence*" is the least important and showed why she placed other criteria higher. In her explanation, she explicitly listed all other criteria and says they were more important because models need to have components and mechanisms, make sure evidence connects to the question, be organized and clear, and explain what is happening. Laila felt that this criterion is least important because it has already been said in these other, more important criteria.

The fifth and last justification category ranked some criteria as specifying aspects of models students already knew and therefore the criterion was deemed less important. For example, the dyad James and Ethan said that the criterion "*not have extra or irrelevant components, mechanisms, or evidence (all should help answer the question)*" was least important because they already knew not to do this:

James:	And this one is pretty much commonsense.
Ethan:	Yeah.
James:	If something doesn't go with your model, then-
Ethan:	Don't put it there.
James:	Yeah, don't put it there.

James and Ethan reasoned that the criterion "*not have extra or irrelevant components, mechanisms, or evidence (all should help answer the question)*" is "commonsense" and "something you already know." As a result, the criterion was given less priority and was placed at the bottom of the list.

Discussion

Epistemic criteria are central elements of scientific practices, including the practice of modeling. Scientists evaluate models in accordance with epistemic criteria, such as fit with evidence and explanatory power. If we are to engage students similarly with epistemic criteria that they develop and are accountable to in the context of a learning community, we need to better understand how students understand these criteria, their importance, and their relative priority in relation to other criteria. Towards that end, we analyzed fifth grade students' justifications of why specific criteria are important and their reasons for rank ordering them. Our analyses show that students were able to develop a class criteria list to guide model creation and revision. Students were also able to evaluate criteria by prioritizing and reasonably justifying why criteria were important. Further, students were able to provide reasonable justifications about criteria as a set and criteria in relation to each other. Some of these justifications included important aspects of criteria lists, such as specificity, redundancy, essential elements, and being encompassed and entailed by others.

Our findings extend previous research, which showed that seventh graders could develop appropriate epistemic criteria for model goodness, by demonstrating that younger students share this competence, and further, that they can prioritize criteria. More significantly, our findings demonstrate that fifth graders have meta-epistemic competence. By this we mean that they are able to reason about and justify epistemic criteria for scientific models. First, students are able to describe the criteria of good scientific models. This is valuable because it means that students are aware of their thinking and are able to articulate ideas about epistemic criteria. This may seem trivial, but such discussions are rare in classrooms, and it is not simple to articulate meta-reasons for complex epistemic considerations (Chinn et al., 2020). Second, students are able to engage in a more sophisticated level of meta-epistemic discourse by evaluating criteria of good scientific models. This was shown by the students' justifications, which reveal that students understand why criteria are valuable. This is a novel finding.

Meta-epistemic competence is an important aspect of scientific practice, and we have demonstrated that elementary school students, as young as fifth graders, exhibit this competence. This is an impressive capacity that instruction can build on. Not only can students describe very reasonable criteria; they can also articulate why their criteria are important in ways that are sensible and compelling. Instruction can attend to these student competencies by engaging students in developing and applying criteria lists to models, and engaging students in meta-epistemic discussions of why these criteria matter, to whom, and under what conditions. In some cases, people differ in the criteria they value and this can lead to deep epistemic disagreement (Chinn et al., 2020). Resolving such disagreement entails reflecting on the criteria the different parties espouse and why. Discussions of this sort, about the relative merits of different criteria, are important yet rare in schools. If we want students to build competence in noticing differences in criteria use, and in arguing about their utility and value, we need to engage them in these kinds of discussions early and often. Our study has shown that even fifth grade students are capable, at least to some extent, of justifying criteria and reasoning about their relative merits.

Abstract: Promoting epistemic agency using problem-based learning (PBL) in science curricula allows students to co-construct scientific knowledge and practices. However, researchers have revealed that teachers struggle to distribute epistemic authority inside classrooms. We use exploratory case studies of two biology teachers' adaptation of PBL units to explore the variation in pedagogical practices that influenced students' epistemic positioning. We analyzed classroom observation notes, teachers' interviews, and teachers' daily reflection notes to identify different instructional approaches. The findings suggest that teachers perceive the opportunities to activate epistemic agency within the same PBL curricula differently. Their pedagogical choices to leverage these opportunities depend on teachers' perception of the more important learning objectives and the structural limitations and affordances provided by the context of the classroom.

Introduction

There is growing interest to promote epistemic agency in science education (Haverly, Calabrese Barton, Schwarz, & Braaten, 2020; Miller, Manz, Russ, Stroupe, & Berland, 2018; Stroupe, Caballero, & White, 2018). Epistemic agency is the ability for students to engage as co-constructors of knowledge in science classrooms (Miller et al., 2018). When engaging as epistemic agents, students display ownership of the knowledge-building process and share the cognitive authority of directing science inquiry with teachers within classrooms (Hardy et al., 2018; Miller et al., 2018; Stroupe et al., 2018). Classrooms that engage students as epistemic agents, empower students to shape the knowledge production practices (Stroupe et al., 2018), thereby, transitioning students from "receiver of facts" to "doers of science" (Miller et al., 2018). Pedagogical practices that engage students as epistemic agents allow students to co-construct science storylines with their teachers and disrupt hierarchies of power in science education (Calabrese Barton & Tan, 2009; Hand, 2012; Rosebery, Warren & Tucker-Raymond, 2015). Epistemic positioning of students also propels a shift in instructional practices from those that engage students in mimicking "correct" canonical science information to adopting strategies that empower students to develop their own ideas (Hardy et al., 2018; Miller et al., 2018; Stroupe et al., 2018). This helps fulfill the larger need of engaging students in disciplinary practices as advocated by the Next Generation Science Standards (NGSS) (NRC, 2012).

However, despite the known advantages of student's epistemic positioning in science classrooms, current classroom practices and learning experiences often fail to promote epistemic agency (Miller et al., 2018; Brown, 2017). Most schools, especially within formal environments, struggle to engage students as epistemic agents (Eriksson & Lindberg, 2016). Supporting student's epistemic agency within science classrooms is a challenge for teachers because of the tensions that arise from maintaining authoritative control over the content while attempting to create authentic opportunities for students to engage with and construct knowledge that is meaningful to them (Braaten & Sheth, 2017; Windschitl, 2002). Teaching science using epistemic teaching practices disrupts traditional power structures within a class (Bang, Brown, Calabrese Barton, Rosebery, & Warren, 2017; Haverly et al., 2020). This kind of teaching requires different pedagogical strategies, to leverage students' ideas for an active knowledge production process within classrooms (Brown, 2017; Miller et al., 2018; Schwartz et al., 2018).

A few potential paths have been suggested to modify teacher instruction for students to act with epistemic agency in science classrooms (Stroupe et al., 2018). One of these paths include teachers adapting science curricula to intentionally allow their students more say over how the community engages in knowledge construction work using problem-based learning (PBL) (Miller et al., 2018; Stroup et al., 2018). PBL provides one avenue for repositioning learners as epistemic agents as it allows for collective responsibility of knowledge building through sharing of students' individual science stories (Stroupe et al., 2018; van Es, Hand, & Mercrado, 2017). It also provides multiple opportunities to shift the epistemic authority from the teacher, wherein power and authority traditionally lie, to the students (Miller et al., 2018; Stroupe, 2014). However, early studies have shown that teachers tend to identify these opportunities differently (Haverly et al., 2020). They often struggle with interpreting and leveraging pedagogical opportunities to engage students as epistemic agents (Barnhart & van Es, 2015; Jacobs, Lamb, & Philipp, 2010). Hence, there is a need to understand how teachers vary in interpreting pedagogical opportunities to position students as epistemic agents within the design of the PBL units (Haverly et al., 2020; Stroupe et al., 2018). Furthermore, there is a need to explore the factors that influence these decisions (Stroupe et al., 2018) in adapting PBL supports to formal science classrooms. To design professional development (PD) supports that scaffold teacher's epistemic instructional practices, we need to understand how teachers vary in their degree of engaging students as epistemic agents within the implementation of PBL units (Miller et al., 2018; Stroupe et al., 2018). In this paper, we explore how two science teachers improvise PBL units on the topic of bioinformatics that had students explore a problem relevant to their community, collect and analyze data from their neighborhood to make inferences about the topic, and propose interventions. We look closely at select movements where the teachers differed in providing opportunities for students to engage as epistemic agents. In this paper, we ask the following research questions: 1) How do teachers' pedagogical practices vary in engaging students as epistemic agents during the implementation of the PBL unit? and 2) What factors influence these decisions?

Conceptual framework

Over the years, researchers have found that students engage with epistemic agency when they contribute to the knowledge-building process while engaging in science practices such as argumentation and experimentation as opposed to replicating the practices modeled by the teacher (Haverly et al., 2020; Zimmerman & Weible, 2018). Also, recent science education studies have found that the learning environment for supporting epistemic agency should be contextualized in a way that values students' ideas as resources in producing useful knowledge in the curriculum (Stroupe, 2014; Stroupe et al., 2018). Miller et al., (2018) detail four opportunities to unpack epistemic agency within the NGSS and argue for these to be specified in the design of the lesson. These are; 1) opportunities to solicit and build on student knowledge as a resource for learning; 2) opportunities for students to build knowledge; 3) opportunities for students to build a knowledge product that is useful to them; and 4) opportunities to change structures that constrain and support action. We use this conceptualization to identify opportunities that existed within the bioinformatics PBL unit. Table 1 shows the definition of each of these pedagogical opportunities and provides examples of how these were incorporated into our PBL unit.

An important characteristic of science curricula that relates to epistemic practices in classrooms is the emphasis on student authority over what counts as knowledge within an activity (Erikson & Lindberg, 2016; Haverly et al., 2020). This kind of teaching requires teachers to notice students' "individual student histories" inside and outside of class (van Es et al., 2017, p. 266). Haverly et al. (2020) explains that teachers make space for students to co-construct knowledge when opportunities for meaningful student discourse and interactions are coupled with visible shifts in epistemic authority from teachers to students. Stroup et al. (2014) recommend an ambitious instructional model, where the cognitive authority of knowledge inside a science classroom is constantly negotiated by both students and teachers. In classrooms characterized by ambitious instruction, teachers give cognitive authority to students by involving students' inputs in framing an argument and evaluating the efficiency of methods employed by the teacher. In contrast, in a classroom setting where cognitive authority is not distributed, the teacher guides students to discover elements of knowledge that the teacher has decided as important. Similarly, Haverly (2020) conceptualizes science teaching across three degrees of distribution of epistemic authorities; (a) co-constructed practices where the teacher and students share epistemic authority, (b) teacher-constructed practices where the teacher maintains epistemic authority, or (c) student-constructed practices where epistemic authority shifts entirely to students.

Teachers make pedagogical decisions to intentionally share (i.e., co-construct) the epistemic authority with students using multiple instructional strategies such as, using "wait time" for students to reflect on their mistake before immediately fixing it with teacher instruction (Haverly et al., 2020) or using collaborative scaffolds that create opportunities for students to critically analyze responses of their peers (González-Howard & McNeill, 2020; Haverly et al., 2020). Another strategy is to use teacher prompts that elicit contradictory responses from students so that they can deliberate about the complexities of the topic among themselves (Haverly et al., 2020; Miller et al., 2014; Stroupe, 2014). Conversely, in classrooms that model teacher-centered pedagogical practices, the visible evidence of shared epistemic authority is minimal. Here, students may be invited to pedagogically share their experiences during the knowledge building process, however, these exchanges do not translate to sharing of epistemic authority as teachers reign control of the class by directly correcting students' mistakes and by using teacher-centered scaffolding such as modeling for students to enact the steps shown by the teacher (Schoerning, Hand, Shelley, & Therrien, 2015; Erikson & Lindberg, 2016). Evidence of student-constructed pedagogical practices, where the epistemic authority completely shifts to students, is limited within existing literature in formal science classrooms (Haverly et al., 2020; Stroupe, 2014). We us this conceptualization to analyze the variation in pedagogical practices adopted by the science teachers in implementing the PBL units.

Methodology

This study is part of a larger NSF-funded project on teacher PD that aimed at integrating scientific research on the topic of bioinformatics in high school science classrooms. In this paper, we conduct qualitative case studies of two science teachers who used different pedagogical approaches to implement the PBL curricula support distributed in PD.

Participants

We worked with two biology teachers, one female, and one male, who taught in different urban public schools in the Northeastern United States. Both teachers were volunteers. The first teacher, Sam, had 15 years of teaching experience, taught ninth-grade biology in a school where students were identified as 39% White, 29% Asian, 16% Black, 5% Hispanic, and 11% other. The second teacher Linda had two years of teaching experience, taught ninth-grade biology in a school where students were identified as 54% Black, 24% Hispanic, 12% Asian, 7% White, and 4% others. All students in both schools were eligible for free or reduced-price lunch (an indicator of income level in the United States). On the state standardized test, students scored 93% and 33% proficient or advanced in biology respectively from both schools.

Context

The bioinformatics PBL unit was anchored in a scientific inquiry to explore the issue of high asthma rates within urban communities. Students were provided with sensors and phones to measure air quality in different locations of their community and analyzed data patterns using Google Sheets and Microsoft Excel. Based on an analysis of collected data, students were asked to propose an intervention to address the air quality issue in their neighborhood. Table 1 provides an overview of the PBL activities and illustrates its alignment with Miller et al. (2018)'s epistemic opportunities. Teachers were given the agency to adapt these PBL units to align better with their individual teaching goals.

Table 1: Definition of Miller et al. (2018)'s epistemic agency opportunities and alignment with the PBL unit

Epistemic Opportunities	Definition	Examples of PBL Activities
Building on student knowledge as resources	Instructional approaches where students' community and culturally based intellectual resources are used for knowledge building.	- Anchoring the study of bioinformatics in the issue of asthma and air quality - a problem highly relevant in the city especially among students of color (Bryant-Stephens et al., 2012). - Group reflection of asthma cases within family and community.
Building knowledge	Instructional practices that position students to engage in the practices of scientists instead of typical roles as passive recipients of information.	- Students work with large online data sets to identify patterns and make inferences about air quality across years. - Students use mobile air quality sensors to collect and analyze data from areas around schools. Then they design proposals to analyze data around their neighborhood.
Building knowledge product that is useful to the student	Instructional practices that provide opportunities to engage in authentic problems in nature that are part of their experience, rather than trying to learn a fact or idea.	- Students identify areas of relevance in their neighborhood using the air quality sensor and app. Then, they draw conclusions about the air quality and its effects on one's community and propose interventions.
Changing structures that constrain and support action	Instructional practices that position students as change agents in the local and global structures that constrain and support tangible action.	- Students present and defend their intervention proposals.

Data source and analysis

We analyzed three data sources: Classroom observation notes; teachers' post-implementation interviews; and teachers' PD daily reflection notes. The classroom observation notes were used to identify the different instructional strategies employed by teachers in implementing the PBL unit. The post-implementation interviews and teacher reflection notes were used to understand the factors that influenced teachers' decision-making process with regard to engaging in practices that positioned students with epistemic authority. We used an exploratory case study methodology (Yin, 2017) to provide qualitatively rich descriptions of instructional practices and classroom implementations that enacted epistemic agency. The classroom observations were organized to group instances that were reflective of Miller's epistemic opportunities built into the curriculum. The data was then deductively coded to identify instances of teacher-constructed strategies, co-constructed strategies, and student-constructed strategies (Haverly et al., 2020). We did not find any instances of student-constructed pedagogical practices. The transcribed data sources were analyzed and triangulated qualitatively to identify themes that could be attributed to the decision and activation of epistemic agency. All analyses were discussed by the research team to validate the themes. Table 2 describes the coding scheme with examples from the data.

Table 2: Coding scheme and examples from the observation notes

Epistemic Opportunities	Instructional Variations in Positioning Students with Epistemic Authority
Anchoring bioinformatics in student's experiences with asthma.	**Teacher constructed strategies:** Class starts with a "do now" question (Do you know anyone who has asthma? What do you know about asthma?). Here, students are asked to agree or disagree with the statement and write down an explanation. The teacher shows a video on asthma giving students a few minutes to revise their statement if their viewpoint has changed and then, introduces the PBL scenario. **Co-constructed strategies:** The teacher elicits student dialogue about family instances of asthma and allows students to engage in conversations about ways in which it affects family health and routine. The teacher creates "affect" around the topic before introducing the line of inquiry of the PBL unit.
Students use mobile air quality sensors and Google Sheets to collect and analyze data from areas around schools.	**Teacher constructed strategies:** Students are asked to make a copy of the data and analyze them by calculating mean, median, and mode. The teacher breaks down these steps and demonstrates them one by one while waiting for students to follow the steps. **Co-constructed strategies:** Students start by looking at the data they collected and write down what they think. Sam explained the units for the particles. Then, showed two *t*-test videos and asked students how the t-test was going to be helpful for their project. Then, students try mean, median, mode, and t-test on the Car-Barn sites data in groups. For the students who completed getting a *t*-test value, they were guided to do a *t*-test with their indoor data. The teacher reminds students that they are researchers to encourage them to work with each other to resolve emerging questions.
Students identify areas of relevance in their neighborhood using the air quality sensor and app. Then, they draw conclusions about the air quality and its effects on one's community and propose interventions.	**Teacher constructed strategies:** Teacher explains the assessment criteria (informal rubric - Full sentences, check grammar; Two sentences for each question; 30 points in total). Teacher provides a sample data chart table on the writing board. Then, the teacher provided a template for how to do data comparison and describe data in sentences. She also explains what data students could compare with examples of Carbon Monoxide and Particulate Matter 2.5. **Co-constructed strategies:** Students analyzed data and discussed ways to help solve the problem of rising asthma rates in Philadelphia. Sam provided a Google Document template for writing the project report, at the same time he

	allowed students to make one of their own. Sam walked around each group to check how students are going to analyze data for their final report. Class ended with sharing what students observed so far and what were some things that students might have done differently with their data collection.

Result

The findings are organized into themes that illustrate how the two teachers differed in their implementation of the PBL activities, particularly in their distribution of cognitive authority within the PBL activity, and to explain the rationale behind these differences. In the next section, we explain how the two teachers differed in the instructional practices employed for the same PBL units.

Variation in teacher instructional practices: Teacher-centered versus distributed epistemic authority

Among the two teachers. Sam adapted the PBL in ways that allowed students to co-construct the science inquiry process by engaging in epistemic pedagogical practices. However, Linda struggled with sharing the cognitive authority of directing science inquiry with the students and instead relied heavily on teacher-centered strategies.

In the classroom that used co-constructed practices, Sam created multiple opportunities for students to take ownership of their science inquiry process. For example, Sam provided students with choices in selecting the context of data collection, setting investigation questions, framing final reports, and presenting their community solutions to the whole class. Throughout the implementation, Sam consistently referred to students' epistemic authority while encouraging student ownership. He also directed students to use their peers as resources when they ran into issues with the use of mobile sensors, and data analysis resources. He used collaborative scaffolding immensely during the data collection and analysis portion of the PBL. For instance, in the lesson where students engaged with online data sets to build inferences about the air quality data over different years. Sam had students freely explore the website and discover various elements of the site and share their observations with the whole class. He also gave students the freedom to choose the years they wanted to compare to infer varying data patterns. During the discussion, he asked students to critique the analysis each group presented. Throughout the activity, Sam kept reminding students of their agentic positioning by telling them that they were researchers of the project and hence should drive their own conclusions. Moreover, when students ran into issues with setting up mobile sensors for data collection and navigating the Google Sheets for recording and analyzing indoor collected data, Sam referred students to direct their questions to peers who showed proficiency for navigating these tools. In his interview, when referring to using collaborative scaffolds, he mentioned,

> I think the part where kids learned from each other went really well. The couple days where I spent going over stuff with Excel, they really taught each other most stuff and how to get through that quicker than if I did it your typical way, where I do the activity with an example and they model it as a whole class. They as a group were good at collaborating with each other. I prompted them to talk to one another when they were stuck. So, I think that part of it actually was one of maybe more the success stories.

Linda, however, struggled with distributing cognitive authority while adapting the PBL to meet the requirements of her class. Linda’s implementation employed teacher-centered practices where students were either enacting practices modeled to them or were engaging in discussions to get to an answer Linda had decided as the correct one. The classroom observations highlighted Linda's reliance on teacher-centered scaffolds to guide student learning during instances where the PBL lessons created opportunities for students to build knowledge. In implementing the same lesson referenced in Sam's class, Linda modeled the usage of the website that hosted the data sets in a step-by-step manner and had students enact the steps. She also asked students to compare data patterns of specific years. There was a limited choice given to students in selecting the years. As a result, there was limited variation among student responses as all students examined patterns of the same year. Also, when questions were raised about the nature of data or Google Sheets usage in the indoor data collection lesson, students directed their questions to Linda, and they were addressed through verbal exchanges between the teacher and the students. Linda emphasized the use of teacher’s scaffolds used in her lessons, in her post-implementation interview,

> My students don't know a lot of the basics in using Microsoft software, or Excel, or any Google applications. So, there was a lot of fundamental knowledge that I had to scaffold for all of the students. There are a couple here and there who just will shut down once they've struggled so much with trying to use Excel, or copy and paste data, or find the averages. So, it is better to guide all students to one or similar kinds of answers, otherwise, it gets confusing.

In Sam's adaptation of the PBL, he made pedagogical choices to engage students as epistemic agents by giving students more agency over tools, context, framing of results, and by giving students space to discuss and critique ideas. He leveraged collaborative scaffolds to guide the class towards the larger goals of the PBL. However, Linda's adaption of the PBL included less student choice and more teacher-centered scaffolds. While Linda provided space for children to share their experiences, these exchanges did not result in sharing epistemic authority with students as all students continued to refer to Linda to correct their interpretations or their science inquiry instead of referring to their peers or oneself as having the authority to direct one's learning.

Rationale for different instructional choices: Navigating around versus adhering to structural limitations

In co-constructed classrooms, Sam prioritized student engagement with content over canonical knowledge. Sam created opportunities for students to engage as epistemic agents while navigating around normative practices of formal classrooms such as limited instructional time and meeting grade-level learning standard requirements. This is because he felt students' engagement with the content mattered more than their ability to recall terms and definitions. When reflecting on the choice of design assignments, Sam stated in his interview,

> Yes, I felt a sense of urgency that I'm going to be behind with the other content that I need to teach in biology and I also don't know if students can actually remember the definitions but the fact that it was an inquiry activity and they got to choose what they were looking at was more important. Early in the unit when we were going over what asthma was, I was getting some real specific questions from students. They were telling me, "Well, this is what happens when my brother has asthma," or "This is what happens when I have an asthma attack." This project was very personal for my students, and it was unique to them.

Similarly, when reflecting on the effectiveness of the PBL implementation, Sam commented,

> I think they got a sense of some parts of the curriculum like the power of information or data, but I am not sure how well they will be able to define bioinformatics for instance. I also think different students hooked on to different parts, that is why I gave them a choice on the format of the final report as well. I think each student has distinct interpretations of the task.

The analysis of co-constructed pedagogical choices shows how Sam navigated through the structural barriers of formal classrooms by choosing to prioritize student engagement over content recall. However, these reflections reveal that Sam made choices about the tradeoffs that resulted from the use of epistemic practices in the classroom such as non-uniform understanding of the content, non-alignment of learning goals with standardized testing requirements, and extending the time allotted to the unit. These tradeoffs were not explicitly addressed in the PBL design. However, in the teacher-constructed classroom, Linda struggled with providing student agency with assessment and activities as she prioritized science content knowledge over engaging with students' individual or lived experiences. She felt her class would benefit more from a stronger focus on content knowledge as it prepared students better for their standardized testing requirements. She said,

> My head was very invested in reaching the goals for each benchmark, which are tests we have to take throughout the year to make sure students are learning the knowledge that's relevant for the Keystones. There's kind of the other side of it with educational research and project-based learning. Principals like those buzz words. They like to see that their students are active and doing things in the community, but at the same time, principals like for their Keystone scores to be high. While I can engage in dialogue with students, I need to ensure they all have the correct understanding of the terms.

While Sam was successful in navigating around normative structures of formal classrooms to engage students as epistemic agents with the PBL, Linda adhered to the structural demands of formal classrooms limiting students' epistemic agency. The PBL was not successful in helping Linda navigate around the tensions inherent to formal classroom instruction. This decision to navigate around or adhere to normative expectations may have been influenced by teachers' prior experience with science teaching or the urgency of standardized testing in the particular grade. Linda, when compared to Sam, was a novice science teacher with 2 years of experience as opposed to Sam who had 15 years of experience teaching science. Linda also implemented this unit in the 9th-grade science, where students were scheduled to take the state science exam in the same year. This was not the case for Sam as he taught in a magnet school that allowed his students leeway in participating in the science exam. These contextual factors may have given differential opportunities for making curricular choices.

Discussion

This paper contributes to the emerging literature on the use of contextual relevant PBL and its efficiency in supporting teachers' use of epistemic practices in science classrooms (González-Howard & McNeill, 2020; Ko & Krist, 2019; Stroupe et al., 2018). Our findings advance the existing understanding of how teachers adapt PBL supports differently to meet their classroom needs and in doing so enhance or compromise students' agentic positioning within science classrooms. Our analysis aligns with findings of other "sense-making" studies which showed that teachers predict and leverage epistemic opportunities within a curriculum differently (Haverly et al., 2020; Rosebury et al., 2015). Sam perceived the PBL topic of asthma to be of personal relevance to his students and hence identified opportunities within the curriculum to share the cognitive authority with his students and leveraged them. On the other hand, Linda perceived the PBL curriculum as a medium to prepare students for their state science exams through enactments of science inquiry practices. These varied perceptions of the PBL influenced the pedagogical choices of epistemic positioning of students, during the implementation.

Both teachers did not engage in student-constructed pedagogy where students participate in equitable sense-making practices. Sam did not cede epistemic authority entirely to his students, rather, he steered his student's conversations and interactions towards the broader learning goals of the PBL. However, he did position his students as people whose opinions and interpretations were worthy of being challenged by their peers, instead of positioning only his guidance and input as the voice of value which is a movement towards shifting cognitive authority and advancing students epistemic agency (González-Howard & McNeill, 2020; Haverly et al., 2020; Miller et al., 2014; Stroupe, 2014). Linda was successful in making room for her students to share their experiences but was not able to share the epistemic authority with her students as she often corrected students directly and asked students to enact the behavior, she was modeling. This reinforces the existing power dynamics of teachers being the owner of cognitive authority and limiting opportunities for students to engage as epistemic agents (Haverly et al., 2020; Miller et al., 2014).

Our paper highlights the tensions between the inherent free nature of open-ended PBL and the normative practices that drive teacher instruction in formal classrooms, which aligns with tensions hypothesized by Miller et al. (2014) and raised by Stroupe (2014). To support epistemic pedagogical practices in formal science classrooms, PD developers should explicitly address structural limitations and provide supports that illustrate or model how epistemic authority can be co-constructed within these limitations to encourage teachers to shift away from teacher-centered scaffolds while adopting PBL curricula to their classrooms.

Spreading GIS-Infused Instruction: A Cross-Case Comparison of Two Instructional Approaches

Katherine James, Northwestern University, katie.james@northwestern.edu
Steven McGee, The Learning Partnership, mcgee@lponline.net
David Uttal, Northwestern University, duttal@northwestern.edu
Bob Kolvoord, James Madison University, kolvoora@jmu.edu

Abstract: This work is part of an ongoing partnership that seeks to create a sustainable infrastructure to support GIS-infused instruction in a large urban school district. In this paper, we report an illustrative cross-case comparison of two teachers' approaches to infusing GIS in their courses. The goal of this analysis is to examine how GIS-infused instruction is adapted in different contexts and to consider the affordances of divergent approaches. Findings illustrate the relationships among organizational context, individual and collective context, particularly teacher identity, and instructional practice in the work of spreading GIS-infused instruction. We also discuss key lessons learned in our partnership thus far and implications for district-level partnerships focused on spread and scale.

Issue addressed and potential significance

Spatial reasoning is an important part of the practices of many disciplines from STEM to the social sciences. However, spatial reasoning is rarely explicitly taught in the K-12 classroom (NRC, 2006) and efforts to design curricula that support the development of spatial reasoning skills have been limited. Given that spatial thinking improves with training and experience these efforts could be extremely beneficial for young learners (e.g., Uttal, Miller, & Newcombe, 2013).

Recent research and standards emphasize the value of Geographic Information Systems (GIS) as a tool for enhancing K-12 students' spatial reasoning (e.g., Jant et al., 2020; NGSS, 2013; NRC, 2006). GIS has been suggested as a tool to support spatial reasoning skills because it enables users to create rich data visualizations and reason about spatial patterns and relationships among different types of data (Bednarz et al., 2008; Bodzin, 2011). Prior work suggests GIS is effective as a learning tool in multiple contexts (e.g., Edelson, Smith, & Brown, 2008). For example, GIS-infused instruction led to better understanding of concepts in energy, climate change, and social science compared to typical instruction in those areas (e.g., Edelson et al. 2008; Lee & Bednarz, 2009). Given the potential value of GIS, a critical next step is to develop effective approaches for incorporating GIS into classroom instruction.

The current work is part of an ongoing partnership that builds on the Geospatial Semester (GSS), a year-long high school course focused on developing geospatial problem-solving skills using GIS and applying those skills to local problems chosen by students (Kolvoord, Keranen, & Rittenhouse, 2019). The goal is to understand whether and how the GSS can be adapted to meet the needs of Chicago Public Schools (CPS), a large, urban school district teaching a variety of content areas and to create a sustainable infrastructure to support GIS-infused instruction in CPS. Given the widespread, career-relevant applications of geospatial technologies, we focus in particular on the CPS Career and Technical Education (CTE) program, which serves groups currently underrepresented in STEM careers, with the goal of building career-relevant GIS skills in the pathways students are already pursuing.

Our work is informed by Coburn et al.'s (2013) conceptual framework of spread and scale (see Figure 1). Spread is defined as the process by which tools, ideas, practices, or programs move to a greater number of people or organizations through both top-down and bottom-up means (p. 3). Coburn et al. consider who spreads, what spreads, strategies to foster spread, and the contexts that influence spread. They also discuss the various levels at which contexts influence spread: individual and collective, organizational, environmental, and policy. In this project, we focus primarily on the individual and collective level, which involves teacher identity, knowledge, and skills, and the organizational level, which includes support from administration and colleagues and availability of technology. Within these contexts, capacity building and participation are key spread strategies. Coburn et al. use the term scale to refer to the intended outcome of spread and note that scale can be defined in several distinct ways, including adoption, replication, adaptation, and reinvention. In the current work, we define scale as adaptation. Adaptation privileges modifications that incorporate contextual perspectives and needs over strict fidelity and seeks to engender widespread use (Coburn et al., 2013). Modifications can be either appropriate in that they reflect the key ideas, practices, or principles or inappropriate, often referred to as "lethal mutations" (e.g. Tatar et al., 2008). Design principles provide the means to guide appropriate adaptations (James et al., 2020).

In this paper, we report a cross-case comparison that illustrates two teachers' approaches to infusing GIS in their courses. The challenge we take up in this paper is to examine how GIS-infused instruction is adapted in different organizational and individual and collective contexts and to understand the affordances of divergent approaches, given contextual differences and local goals for adaptations.

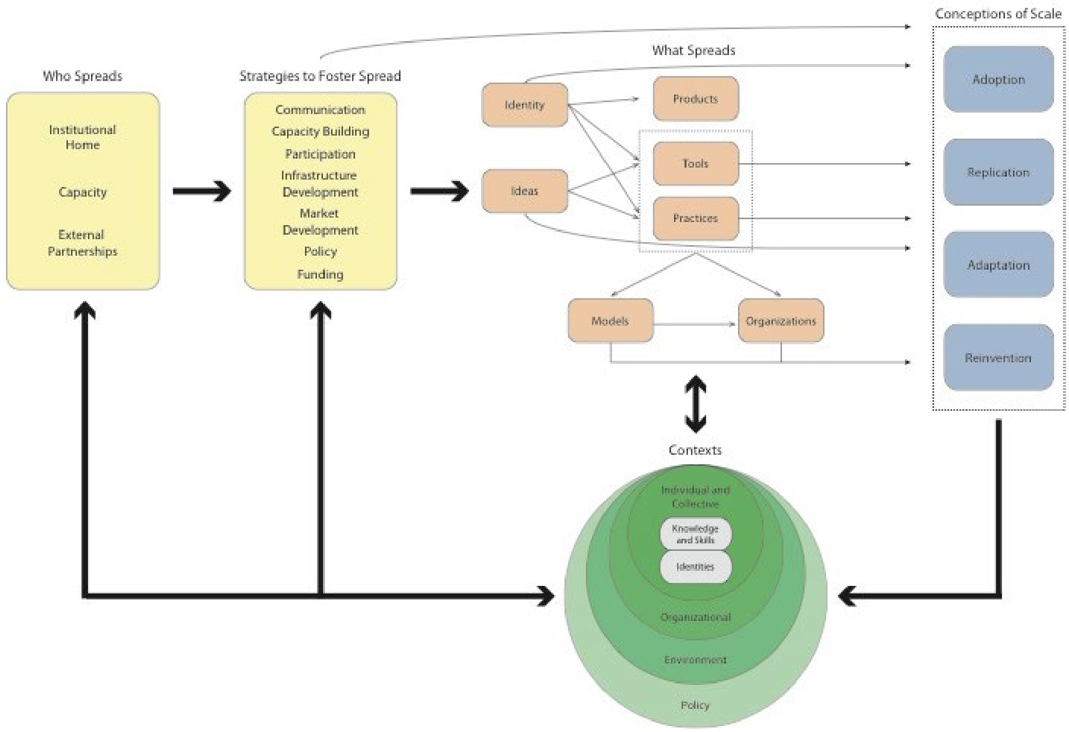

Figure 1. Coburn et al.'s (2013) spread and scale framework.

Methodological approach

Research context

At the outset of the project, we established an ongoing partnership with the CPS CTE office. During Spring 2018, the researchers met with the entire CTE team, including office leadership as well as representatives from the career pathway clusters, such as cluster managers, curriculum specialists, and implementation specialists. We took a top-down approach to recruitment at the organizational level by partnering with the CTE office to identify pathways and courses that could benefit from the infusion of GIS. We initially sought to adapt and implement the original GSS model, which involves an entire year-long GIS course focused on extended student-driven inquiry projects. The partners determined that the CTE capstone course, a year-long, project-based course taken by all seniors in the CTE program, would be a natural fit for this model. Six CTE pathways were initially identified as targets for the year-long GIS course: Pre-Engineering, Entrepreneurship, Agricultural Sciences, Health Science, Construction and Architecture, and Law and Public Safety. Managers of each of these CTE pathways then invited teachers to participate.

In the early stages of the project, it became clear that additional GIS capacity building was needed to help students build the complex GIS and spatial reasoning skills that would be drawn on in the year-long GIS course. To this end, we began incorporating freshman and sophomore content courses outside of CTE that could support GIS capacity building and facilitate multi-year GIS trajectories at schools. In other words, we shifted from spreading the entire GSS model to spreading relevant tools and practices. To facilitate this shift, we began additionally using a bottom-up strategy to recruit individual teachers based on interest. Teachers in the social sciences and computer science chose to join the project.

Professional development and lesson co-design

Teachers participated in a series of professional development workshops, including a five-day summer workshop and one-day mid-year workshop during the 2018-2019 school year (year one) and a four-day summer workshop during the 2019-2020 school year (year two). During the workshops, GIS technical skills were taught through challenge tasks and skill-building activities. The workshops also incorporated support for lesson planning and implementation, including structured peer feedback routines, small- and large-group discussions of classroom video excerpts (e.g., Sherin & van Es, 2005), and metacognitive reflections on and discussions of teachers' instructional practice. Throughout the workshops, teachers explored how to infuse GIS in ways that align with their context, content, and instructional goals.

Teachers partnered with the researchers and local GIS mentors to develop course maps that lay out a year-long sequence of GIS-infused lessons and pinpoint which units those lessons align with in their course. They then co-designed lesson plans and classroom materials for each of the lessons in their course map and implemented those GIS-infused lessons in their courses.

Case study context

As teachers carried out the work of designing and implementing GIS-infused lessons, we noticed differences in organizational as well as individual and collective contexts, particularly teacher identity relative to GIS-infused instruction. The current study focuses on two different school contexts where contrasting teacher identities emerged: Jackson High School and Addison High School (all names are pseudonyms). Jackson is a high-ranked selective enrollment school located in the center of the city. The racial and ethnic makeup of the school's roughly 1900 students is 40% White, 29% Hispanic, 14% Asian, and 11% Black. At Jackson, there was no organizational-level GIS initiative. Teacher recruitment was done through the social sciences department based on teacher interest. A total of three teachers from Jackson, each of whom taught a different area of social science, initially participated in the project. Thus, each GIS-infused course at Jackson was a standalone course. At Jackson, the teachers viewed themselves primarily as content teachers and, thus, framed GIS as an instructional tool to convey disciplinary content.

Addison High School is a wall-to-wall CTE magnet school located on the periphery of the city. The approximately 820 students are 48% Black, 32% White, and 18% Hispanic. At Addison, there was organizational-level interest in developing multi-year GIS trajectories and infusing GIS into all of the CTE pathways at this school. Indeed, the principal was already aware of GIS and saw the value of integrating GIS school-wide. He mandated that all CTE teachers and several sophomore-level teachers that could support capacity building courses attend the year one professional development workshops, which were also hosted by the school. Initially, seven teachers, including five CTE teachers and two sophomore-level teachers, participated in the project. At Addison, the teachers identified as both GIS technology instructors and content teachers. Thus, they viewed the development of GIS skills and content understandings as equivalent instructional priorities.

To facilitate a cross-case comparison, we selected a course that was common across the two schools: AP Human Geography. We focused on the AP Human Geography teacher from each school with the goal of comparing their approaches to GIS-infused instruction, given noted differences in the organizational and individual and collective contexts. The two teachers, Mr. Bradley and Mr. Mitchell, each co-designed and implemented a different GIS-infused AP Human Geography course. Both teachers implemented their GIS-infused lessons in all sections of their 10th grade AP Human Geography course during years one and two. Mr. Bradley, who is a teacher at Jackson High School (selective school), implemented seven lessons during year one and four lessons during year two. All lessons were a single class period in length. Mr. Mitchell, who teaches at Addison High School (CTE school), implemented five lessons during year one and six lessons during year two. Lessons ranged from three to seven class periods in length.

Data sources

Consistent with design-based research, we used micro-ethnographic methods to observe and document lesson implementation, focusing on teaching and learning processes. Data from the classroom observations include field notes, video, and classroom artifacts, such as lesson materials and student work. At the end of year one, we conducted hour-long, semi-structured interviews with each teacher with the goal of understanding their rationale for and reflections on their design and implementation process. The classroom observation field notes, videos, and artifacts and teacher interview videos constitute the data sources for this paper.

Analytic approach

The classroom observation field notes, videos, artifacts, and interview data were compiled chronologically into case files for each teacher. The researchers engaged in repeated readings and re-readings and thematic summarization of the case files. Analytic memos were written to describe patterns and themes in the data, focusing on each teachers' approach to GIS-infused lesson design and implementation.

To more closely examine differences in teachers' instructional practices, we selected one lesson implemented by each teacher in the middle of year one. These focal lessons were selected because they illustrate the contrasts noted during earlier analysis and are representative of each teachers' instructional approach. The focal lessons were further analyzed through research team debriefing. During the debriefing session, we reviewed an observation summary, which included a description of each lesson and a focal theme, relevant artifacts from the classroom observation data, and a set of guiding questions to structure the discussion around the theme. The research team then analyzed the data with the goal of understanding the affordances of each approach and generating new insights.

Finally, the cases were compared to identify distinctive characteristics of each teachers' approach. The findings presented here are of the two case studies and cross-case comparison.

Findings

The two cases discussed here illustrate variations in the teachers' approaches to GIS-infused content instruction. Table 1 provides an overview of the key differences between the two cases with respect to context, lesson design, learning goals, role of GIS, and timing.

Table 1: Case study teachers

Case	Context	Lesson Design	Learning Goals	Role of GIS	Timing
Mr. Bradley	Selective school, standalone course, content teacher identity	Focused, content-specific lessons	Content-relevant spatial reasoning	Extremely user friendly, minimize interaction with technology	Focus on efficiency, balance with AP content coverage
Mr. Mitchell	CTE school, organizational-level GIS initiative, GIS instructor and content teacher identity	Topical but open-ended lessons, focus on student-driven inquiry	Investigate topics of interest, GIS skill building	GIS as tool for inquiry, productive struggle to figure out GIS skills	Open-ended, space for exploration

Case #1: Mr. Bradley

The focal lesson was the fourth GIS-infused lesson in Mr. Bradley's course. He provided a set of three pre-made maps that contained the information and afforded the content-relevant spatial sense-making he wanted students to engage in. The three maps contained information about 1) world religions, 2) climate, and 3) elevation. To structure students' interaction with the maps, he provided a series of questions that moved from data gathering to analysis and interpretation, particularly noticing and understanding the targeted spatial patterns. In this lesson, students were asked to determine how geographic factors contributed to the spread of a list of religions, focusing on the contrast between universalized religions (e.g., Christianity, Islam) and ethnic religions (e.g., Hinduism, Igbo). Students toggled between the maps to qualitatively analyze the information, focusing on identifying corresponding areas of the maps and understanding relevant spatial patterns. Students worked independently or in pairs to answer the questions based on the information in the maps and then shared their insights and questions with the class. In the excerpt below, the world religions map is projected on the screen and zoomed in on the area surrounding the Himalayas. The teacher poses one of the questions from the activity and the class discusses the spatial relationships between geography and the spread of religion in the region.

Teacher:	Why didn't Buddhism go south and why didn't Hinduism go north? What's blocking the diffusion of the religions here, Charlie?
Student 1:	The Himalayas.
Teacher:	What...are those?
Student 1:	Mountains.
Teacher:	Mountains! The tallest mountain range in the world and they kind of extend this way [gestures east along the Himalayas on the map] That's why these areas have maintained their traditional beliefs because, again, the mountains

	and very tropical areas and very difficult to get through so these areas never were really touched by Buddhism. Instead, Buddhists went around using the ocean and thus they reached over here. Why on earth then would these Buddhists be so different than the ones from the north, Maria?
Student 2:	There's no interaction between them so they each established different religions.
Teacher:	My budding Geographers, you're so close to blossoming. It's beautiful. Right! Look! You have mountains, high elevation...the only way you can reach these areas is through traders going through the ocean, right? So thus, these areas have maintained and then you see a whole different version of Buddhism because there's less interaction.

As the transcript illustrates, this lesson enabled students to make key insights into the spatial patterns and relationships underlying the spread of world religions. Indeed, this GIS-infused activity meaningfully enhanced their understanding of the content while allowing them to build spatial reasoning skills through GIS. As briefly mentioned in the transcript, Mr. Bradley framed GIS as a tool for thinking like geographers, emphasizing that maps are an important source of information in geography and, while they can draw inferences about patterns from this data, there are multiple valid interpretations and a need to corroborate the information with other sources. This rooted the activity in disciplinary practices and connected it to the other work that students were doing in this course.

As reflected in the focal lesson, Mr. Bradley's GIS-infused lessons commonly engaged students in using GIS to analyze content-relevant spatial patterns. These lessons were strongly connected to the content and thoughtfully integrated into units where there were important spatial relationships, such as global patterns, underlying the geography content. In discussing his goal for using GIS in his course, he emphasized building spatial reasoning skills and enhancing students' content understandings through analyzing spatial patterns:

> Teaching human geography, I understand the value of having that spatial awareness and understanding, like, how two things might be related to each other if they're happening in the same spot. I'm trying to get kids, you know...my students, curious about those types of connections to try and figure out why things are the way they are *where* they are. Right? So, we're worried about the location, not just why things are happening.

Importantly, he also indicated that his goal in using GIS in his course was to leverage its affordances for enhancing understanding, rather than building technical skills. This approach to GIS-infused instruction was shaped by the learning goals, content coverage expectations, and time limitations associated with this AP Human Geography course:

> With AP Human Geo there's just not the time to really get kids to kind of work with the software...I just wanted kids to make those connections, it was very basic. I wasn't interested in getting them to learn the software. I was more concerned about learning that spatial awareness skill.

Overall, Mr. Bradley's approach to GIS-infused content instruction focused on efficient, user-friendly lessons. His lessons minimized the time commitment needed and enabled him to balance the GIS work with the content coverage and learning goals of this AP course in a selective enrollment school context. This approach also minimized the GIS technical skills required of both teachers and students, making the lessons usable by GIS novices without extensive training. These lessons reduced the GIS learning curve and successfully avoided "in the moment" technology snafus that can make GIS challenging to use in the classroom. At the same time, these focused, content-driven lessons effectively engaged students in content-relevant spatial reasoning. Indeed, Mr. Bradley's GIS-infused lessons engaged students in reasoning about spatial patterns and relationships in ways that meaningfully enhanced their understanding of the content.

Case #2: Mr. Mitchell

The focal lesson in Mr. Mitchell's AP Human Geography course was the third in the GIS sequence. In this lesson, which took place over four class periods, students independently explored GIS to investigate a historical human migration. The teacher provided a list of possible topics, vetted data sources, and a set of questions to structure and constrain the task, but students were allowed to choose any human migration that interested them. Students were asked to use GIS to create any three maps and a storymap that told the story of that migration. Storymaps are a GIS tool that allows users to embed maps, videos, photos and other media within a narrative to create a dynamic, interactive presentation that interweaves maps with written analysis. Students had three class periods to explore GIS in small groups and create their storymaps. During this time, the teacher modeled key practices and provided support as needed, but the inquiry was almost entirely student-driven. Indeed, students explored GIS to identify and analyze relevant data and worked together to figure out the technical skills they needed to create their maps and storymaps. On the fourth day, students presented their storymaps orally to the class. The storymaps that students created included maps of key locations and routes involved in the migration and analysis of the factors (e.g., political, geographical, historical) that may have contributed. Many students chose to focus on migrations that were personally relevant, such as their own family's migration.

As illustrated in the focal lesson, Mr. Mitchell's approach to GIS-infused instruction was characterized by exploratory, student-driven inquiry around content-relevant topics. He designed tasks that provided scaffolds, such as vetted topics and data sources, but enabled students to independently explore their interests. In this course, students also commonly used GIS to create their own maps and storymaps, which were presented to the class at the end of each lesson. For example, in their storymap about the dust bowl, one group included a primary source photograph as well as an interactive map with early 20th century county population and agricultural land amounts data for the Great Plains states to illustrate key routes and factors involved in the migration (see Figure 2).

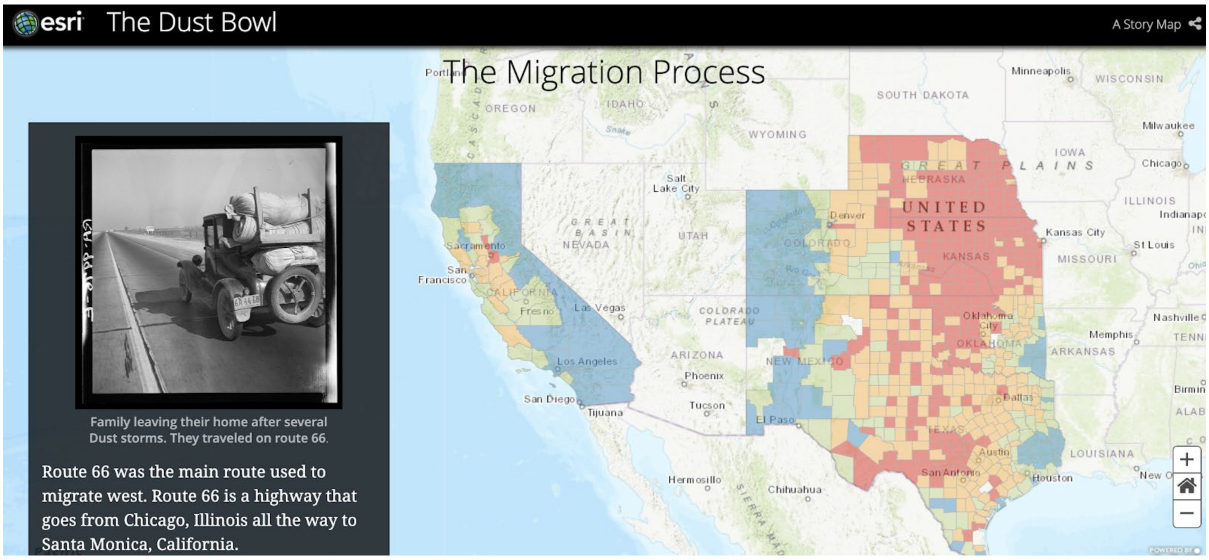

Figure 2. Section of a storymap created by students during the focal lesson.

While creating maps and storymaps introduced additional challenges, it also enriched students' understanding and experience of GIS and enabled them to share and discuss their findings with the community. Indeed, Mr. Mitchell's lessons created space for students to struggle productively and figure out GIS on their own while investigating topics they care about. In discussing his instructional approach, he emphasized the value of exploration and productive struggle for teaching and learning with GIS:

> My teaching style is that they've all got to struggle themselves and they get through that struggle for the most part and they end up doing better. I think it went pretty well, I was really impressed with the stuff they came up with...As we got further and further, I just said ok this is what we're gonna do and then they already had ideas about what layers am I gonna find for that or how am I gonna set this up...it was just them getting the assignment and then them creating and making their own different things.

Indeed, Mr. Mitchell's lesson design motivated and enabled students to do the work of learning GIS. As a result, they developed valuable, real-world GIS-based technical and problem-solving skills:

> What I like about it is after you do [GIS], like we've been doing [GIS] all year, they become little experts...now they actually know more about it than I do...I love seeing that. Giving them something they can actually use in their endeavors forward, regardless of what they actually do.

This exploratory, student-driven approach to GIS-infused instruction, while time-consuming and perhaps challenging to orchestrate, struck an important balance of freedom and structure. Mr. Mitchell's lessons allowed for personalized learning experiences in which students had the space to explore different paths based on their interests and become immersed in that area of the content. As a result, students meaningfully connected with and more deeply understood the content, which also motivated them to develop the GIS technical skills needed to investigate and communicate about their topic of interest. The development of expertise in GIS laid the foundation for application of GIS skills within subsequent CTE pathways.

Conclusions and implications

This cross-case comparison furthered our understanding of the relationships among organizational context, individual and collective context, particularly teacher identity, and instructional practice in the work of spreading GIS-infused instruction. Although they taught the same course, Mr. Bradley and Mr. Mitchell used different approaches to infusing GIS into their instruction. One teacher foregrounded content-relevant spatial reasoning while the other privileged exploratory, student-driven inquiry. Importantly, GIS was also positioned differently in their organizational and individual and collective contexts. Mr. Mitchell's course was part of an organizational-level initiative to develop multi-year GIS trajectories. Specifically, his instructional goal relative to this initiative was to build capacity and prepare students for using GIS in their CTE courses. Thus, he identified as both a GIS instructor and a content teacher and viewed GIS skills and content understandings as equally important in his course. This teacher identity may have shaped his instructional practice, leading to a focus on developing GIS skills through content-relevant, student-driven inquiry projects. In contrast, Mr. Bradley's standalone course was neither supported by earlier GIS capacity building courses nor connected to future courses in which students would apply the GIS skills they had learned. Given this organizational context, he primarily identified as a content teacher. Therefore, only minimal time could be devoted to learning the GIS technology and the focus was instead on building content understandings through the tool. Thus, the organizational and individual and collective contexts in which the GIS-infused instruction occurred may have shaped the specific practices and purposes for using GIS.

This work also underscored the importance of capacity building and adaptation in facilitating spread. With respect to "what spreads", we shifted our focus from the entire GSS model to tools and practices in the early stages of the project. This gave teachers flexibility in the co-design process to tailor their approach to their context and allowed for both of the appropriate adaptations examined in the cross-case comparison. In this way, expanding to incorporate capacity building courses and focusing on adapting tools and practices enabled us to further the spread of GIS-infused instruction in CPS.

In terms of our ongoing district-level partnership, this work also emphasized the value of participation. As is common in large urban districts, department restructuring, teacher turnover, and attrition have occurred. However, in areas where we had a critical mass of team members involved, we have been able to leverage the relationships we had developed and the capacity we had built to continue the partnership in spite of these organizational changes. Indeed, we have found that involving more stakeholders, from individual teachers to department leadership and central office staff, in a partnership leads to greater stickiness and potential for spread. For example, after significant restructuring occurred in the CTE department, we were able to continue our work because the new CTE director was involved in our partnership and planning discussions from the beginning. Additionally, given the success of Mr. Mitchell's and other teachers' capacity building courses at Addison High School, there is ongoing interest from the principal and teachers in expanding the role of GIS at this school.

The next phase of this work will entail revisiting which CTE pathways are the best fit for infusing GIS with the goal of developing both GIS-infused capacity-building and year-long capstone courses for those pathways. We also plan to gradually shift "who spreads" to the teachers and organizational leadership, rather than the researchers. To this end, we will continue to develop our current teachers into teacher-leaders who can train new teachers to implement the courses they've developed with the goal of creating a sustainable infrastructure to support GIS-infused instruction in CPS.

Abstract: Codable robots are now popular toys for families to play with at home. However, during play with codable robots, children may confront novel mathematical and spatial concepts that are central to achieving their coding goals. This work focuses on how parents use multiple modalities in representations with their children to elucidate and make meaning about these concepts. We present three episodes from a corpus of video recordings of parents and children completing a playful coding activity together in their homes. Our analysis reveals how parents support children during meaning making by strategically coordinating multiple modalities of communication, which become more concrete throughout the episodes. These concrete modalities, including physical artifacts and embodiment, support children's understanding of spatial and mathematical concepts, which facilitates their continued play with the robot.

Introduction

Recently, the popularity of codable robot toys in homes has grown exponentially. Codable robots are small robotic toys that children control with programming apps (Bers, 2010). These toys are designed to engage computational thinking skills, such as problem scoping, iterating and debugging, and computational thinking concepts, such as sequencing and logic (Brennan & Resnick, 2012). To date, research on children's play and learning with codable robots has primarily been conducted within formal learning environments (Ohland et al., 2019). However, there are many attributes of the home that are not available in schools which may contribute positively to children's learning with these toys. In particular, the availability of parents may shape children's thinking and learning (Rogoff, 2003). Thus, we examine parent–child interactions during play with a codable robot at home and ask how pairs communicate and make meaning about computational concepts that are central to their coding goals.

Codable robots may be ideal for children's learning at home because they afford constructionist principles like learning-through-doing (Papert, 1980). During play with codable robots, children practice generating procedures by setting their own goals for their robot's behaviors. The child must engage in problem solving to translate these goals into logical computational sequences. Because the coding programs associated with the robots use block-based codes, children are able to prioritize their attention on arranging commands selected from a list, rather than on syntactic elements like punctuation. As a result, children can more readily test and iterate their code. During testing, children receive visual feedback that connects their block-based codes to tangible objects and observable events, revealing errors and inspiring reflection and iteration (Bers, 2010; Papert, 1980). Essentially, the clarity of the block-based codes paired with the tangibility of the robot creates an accessible way for children to practice computational processes.

However, knowing how to program their robot to may require engagement with spatial and mathematical concepts. For example, children often need to insert numerical values into their codes to indicate the distance, speed, and direction at which their robot should travel. Despite the tangibility of the robot, children may be challenged to connect these spatial and mathematical concepts to how their robot moves, resulting in impasses in children's coding process. Yet due to the possibilities for fun and play involved in making a robot move, children may feel particularly motivated to overcome these impasses (Papert, 1980). Nonetheless, children may need additional support to apply spatial and mathematical concepts to continue making progress toward their goals. At home, parents may work with their children to overcome these impasses together, even though parents may be new to coding or may not have established pedagogical tools for supporting their children during coding activities. Thus, we ask how parents and children make meaning about spatial and mathematical concepts when working to overcome impasses during a coding activity. To answer this question, we virtually observed parents and children completing a playful coding activity with a robot together in their homes. This activity presented parent–child pairs with spatial and mathematical concepts that fell within children's zone of proximal development (Vygotsky, 1978), such that children could make meaning about these concepts with the help of a parent.

Framework

We draw from work that considers a sociocultural approach to learning (e.g., Rogoff, 2003; Vygotsky, 1978), which emphasizes that knowledge is co-constructed through social and conversational exchanges. Each person in a social context contributes to the learning through their unique knowledge, skills, and repertoires of practice. For children, the social context of the home environment includes the availability and contributions of parents, who provide a critical social context for children's meaning making and knowledge construction. Parents contribute to meaning making by taking on a guiding role, involving asking questions and directing children's attention (Callanan & Oaks, 1992; Eberbach & Crowley, 2017). During learning interactions, parents closely monitor and assist with their children's understanding and progress with a task by interpreting their verbal and nonverbal cues while attending to subtleties of the interaction (Goodwin, 2018). During play with codable robots, this monitoring behavior may allow parents to provide support to children in moments of impasse.

To provide the support necessary to overcome coding impasses, parents may call on the material artifacts and tools in their homes. In problem solving situations, such as coding a robot, cognition can be distributed among available material artifacts in the environment. People interact with these artifacts in social ways through embodied movements and actions (Hall & Stevens, 2015; Hutchins, 1995). Moreover, material artifacts support collective thinking by facilitating the construction of a shared visual representation, which promotes intersubjectivity and a common understanding of the relevant concepts (Stevens & Hall, 1998). A potential barrier to achieving intersubjectivity with material artifacts is that these objects and representations may be cognitively opaque cultural forms, such as complex tools (Goodwin, 2018). When these barriers arise, more experienced learners can support less experienced learners in using and understanding these forms to achieve intersubjectivity.

In addition to material artifacts, parents use a variety of strategies, many of which can be very subtle, to attune to their child's understanding and find alternate means of explaining concepts. These strategies are often embedded in various forms of communication, such as talk, gestures, the use of physical artifacts, and subtle bodily movements to direct children's attention (Tulbert & Goodwin, 2011), and could easily be overlooked. Studies of multimodality (Kress, 2010) inform our work because they help us tend to the affordances and functional specialism of these various *modalities* of communication and provide additional clues to *why* parents and children rely on different modalities at different times and for different purposes to convey meaning. Often, modalities are layered and used simultaneously or in contrast to nuance meaning (Kress, 2010). Given that children's meaning making about mathematical and spatial concepts can be difficult to elicit verbally in the context of a computational activity, we look closely at how parent–child pairs orchestrate various modalities as an indication of how the pair are making meaning together during their task. Thus, we implemented a method that facilitated close examination of these elements, namely interaction analysis. This microgenetic method offers a more fine-grained and systematic approach to understanding how learning happens interactionally.

Methods

We delivered a materials kit, containing a Sphero Bolt robot, two tablets (one for communicating with researchers and recording the process, and another for controlling the robot), and a felt rug with a map of an imaginary town, to families' homes. During the study session, we guided families through the setup of materials, led a short tutorial on how to use the Sphero, and facilitated participation in a thirty-five-minute coding task. This task required pairs to "take their robot on a trip" to different locations on the floor map. Researchers turned off their cameras and microphones and took field notes throughout the activity. The tablet used to control the robot captured the pairs' on-screen coding activities via a screen recording app. The second tablet was mounted on a tablet stand to record families' interactions and movement through Zoom's recording feature. For analysis purposes, the videos from both recordings were synced, enabling simultaneous viewing of the families' activities, interactions, and code.

Basing our analysis on traditions of interaction analysis work (e.g., Erikson, 2006; Jordan & Henderson, 1995) we began by taking field notes during observations of the pair's interactions and continued as we re-watched the video recordings alongside the pair's on-screen code inputs. We grounded our observations and notes in a variety of modalities of interaction, which meant tending to details like changes in the pace of the activity, shifts in bodies, and evolving expressions of affect as indicators of important moments. In this way, we located key moments where children relied on assistance from their parent to overcome a challenge in their computational tasks. Using these aforementioned cues, we chose episodes that we saw as beginning with initial moments of impasse in achieving the activity objectives and concluding with moments of resolution. Then we generated multimodal transcripts to document content and characteristics of talk, gesture, gaze, and manipulation of material artifacts and the on-screen code. We relied on varied transcription styles allowing us to tend to and report on the information that we observed was relevant to the participants during their interaction. Through careful attention to these transcripts during interaction analysis work, our research team documented and shaped our analysis by considering the sequence and context of each utterance and action, and how the interaction progressed towards a solution. This method of collaboration allowed us to draw on interdisciplinary expertise from the areas of learning sciences, developmental psychology, and computer science as we engaged in the process of discovering meaning making in the interaction. We see this spiraling process of data analysis (Creswell & Poth, 2016) as part of our foundation for identifying and refining the foci of our ongoing work, and also as our effort to see and notice meaning making happening from the perspectives of both the parents and the children (Hall & Stevens, 2015).

Findings

The following episodes show parents and children co-constructing visual representations and coordinating their interactions around those representations to understand mathematical and spatial concepts related to their task. Our findings provide detailed descriptions of how and why this process helps the pair to overcome moments of impasse. Similarities among these episodes reveal patterns in the interactions and demonstrate ways that parents and children use everyday meaning making to solve problems. The differences demonstrate the adaptability of this process in response to the nature of the concepts the pair encounter and the resources available to them.

Episode 1: Co-creating a computational plan using a durable representation

This segment of interaction follows Landon and his mother as they plan the trip their robot will take on the map (Figure 1a). The pair agree their robot will visit six non-adjacent destinations. These criteria play a role in how they choose their destinations while planning. Landon begins by communicating that his plan involves moving the robot from a house to the swimming pool, and then to school, but he soon demonstrates difficulty by starting over several times. As he recites this plan, his mother gazes at each location on the map and responds to him verbally. This creates a back-and-forth flow of talk consisting of his supplied information, her response, and their changing tones (see Table 1). At the moments when his mother is following along, she provides verbal affirmation (e.g., lines 2 and 6). When she is not following along, she pauses their flow (lines 4 and 18) with questions meant to clarify the locations to which Landon is referring. At these moments, Landon responds by recruiting gesture (Figure 1a), which he eventually adds to his communication of every destination. In line 10 the mother's pause serves to draw Landon's attention towards the adjacency of his two sequential stops, which violates one of their established criteria. On Landon's third attempt, his mother halts their sequence of talk and shifts her orientation away from their activity on the map by sitting up and looking around the room while looking around for tape and a marker to label their routes (line 24). She recruits material artifacts for co-constructing a visual representation to help keep track of their plan, allowing the pair to proceed with more certainty (Figure 1b).

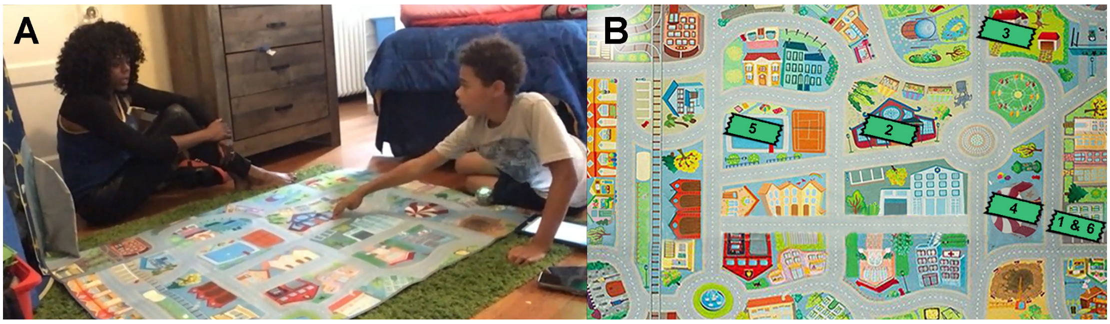

Figure 1. Landon gestures to refer to stops on his route (a). Recreation of Landon's final route (b).

Table 1. Transcript of Landon and his mother discussing the procedure for their code.

Line	Talk	Action
1	Landon: Right. So the ↑swimming pool.	
2	Parent: Yeaa↑ah	*moves gaze to swimming pool)*
3	Landon: To schoo↓ool.	
4	Parent: (.) Where's school?	*searches the map with gaze*
5	Landon: Hhh. Um, so actually- so- to our ↑house. to ↓school	*points to each spot as he names them*
6	Parent: Okay.	

Line	Talk	Action
7	Landon: To the swimming pool	
8	Parent: Right.	
9	Landon: And then-	
10	Parent: Oh wait. But they can't be right next to one another.	*points back and forth between spots*
11	Landon: °Oh° ((grunted))	
12	Parent: ↑It's okay.	
13	Landon: So, let's go to our ↑house.	
14	Parent: Yea	*starts following stops with gaze*
15	Landon: To the. ↓School	
16	Parent: Right	
17	Landon: To Craig and ↑Chris' house.	
18	Parent: Which is?	
19	Landon: Right here	*points to spot*
20	Parent: Okaaay	*places her finger on the spot also*
21	Landon: To. The Circus? (.) Which is right here	*points*
22	Parent: Mhmm.	
23	Landon: And toooo ↓the swimming pool.	*points*
24	Parent: Okay, so you know what we should do?	*sits up and looks around*

Note. In this first episode, we use a modified version of Jefferson's (2004) transcription notation to emphasize features of talk. Arrows represent rising or falling pitch, dashes mark cut-offs, degree signs enclose quieter talk, and a period in parentheses marks a short pause.

At a phase in their activity when the pair had to establish and agree on specific plans, the meaning that was communicated between them to achieve intersubjectivity happened interactionally and was built step-by-step with each utterance and action. Over time, pairs successively layered modalities of communication to offer clarity and stabilize understanding of their shared plan (Stevens & Hall 1998). Accordingly, the pair incorporated more physical and durable representations as time progressed, which leveraged their respective affordances towards more effective descriptions. They started with talk, making use of specific organizational features of their exchange like sequenced turn-taking and patterns of shifting intonation (Goodwin & Heritage, 1990). These subtleties allowed them to specify points where their understanding needed alignment for continued cooperation. To further align this understanding, they next relied on gestures (pointing) and then material objects (tape). This material numbering system had several affordances allowing them to carry out their task effectively. Their placement helped visualize the sequence of stops with a durable representation, yet their placement was malleable, which reserved room for changes to the plan. The labels also highlighted the spatial relationships necessary to confirm that they were aligning to the non-adjacent stop criteria.

Background information for the next two episodes

In the following episodes, parents and children are working on their code and have set a critical variable for navigating their robot called a *reference heading*. Thereafter, *heading commands* that incorporate numerical heading values tells the robot which direction to move. Initially setting a reference heading allows the child to arbitrarily decide a direction at which the robot is facing forward, or at zero degrees (0°). All subsequent heading choices within these individual codes are in relation to this global reference direction. For example, the code *Spin* asks children to input a heading. If the child inputs *90°,* the robot will turn ninety degrees with respect to the forward-facing direction chosen for the reference angle. Setting headings is central to the following episodes.

Episode 2: Employing embodiment to make sense of headings

Alan and his mother have set their reference heading to the direction facing away from the wall and are troubleshooting the headings needed to move their robot from the police station to the train station (Figure 2a). After a few missed attempts, Alan's mother attempts to clarify by tracing the desired route by pointing from "the police station" (Figure 2b) to "the train station" (Figure 2c). However, Alan's gaze is instead fixated on the tablet as he inputs a new heading for another iteration, which does not go as planned. His mother now suggests that he sits against the wall while physically moving him to align his body's forward-facing position to match the direction they set as zero before she tries to explain again (Figure 2d). After another attempt from his position against the wall, Alan's mother leans over, again demonstrating with her hand the direction the robot needs to go. However, at this moment, her speech and physical orientation are not aligned with Alan's perspective (Figure 2e), and his next result is still off. Then, Alan's mother demonstrates a reflexive awareness of how she can respond differently to her son's understanding by recruiting a new modality of communication (Goodwin, 2000), insisting that they stand up together to embody the robot in the same position on the map. Facing their reference heading while looking together at the tablet (Figure 2f), she shows Alan with her arm that the angle is behind and to the right. With this embodied enactment, he finally makes sense of the values and inputs *116*°, a heading that works.

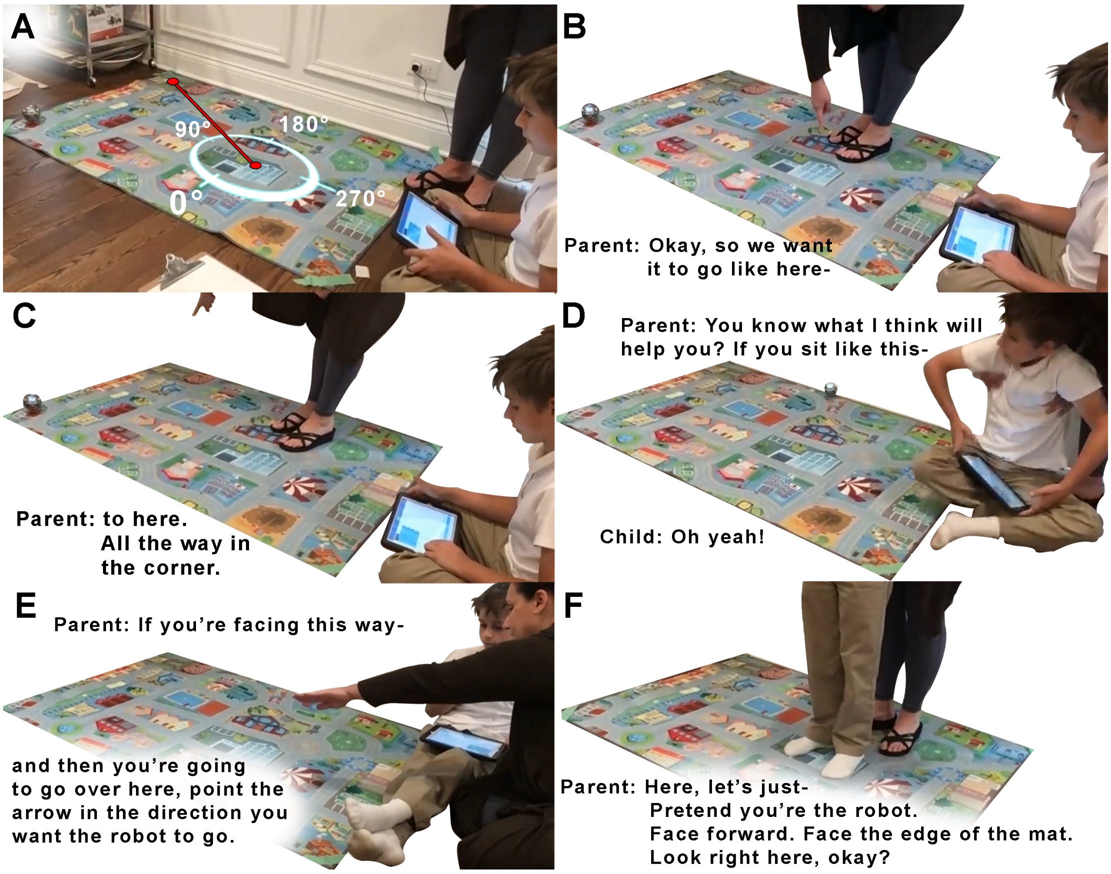

Figure 2. Alan and his mother embody the robot position to understand headings.

The tangible representations of a walkable map, along with the observable and physical outcome of the code enacted on it, allowed the pair to share knowledge and grapple with spatial and mathematical relationships of angles and headings (Horn, 2018; Ramey & Uttal, 2017). At key moments, Alan's mother led their meaning making through her multimodal communication, facilitating Alan's exploration of spatial relationships. By attuning to Alan's understanding and responding reflexively, she situated elements of their code in the material environment around them, providing rapid just-in-time feedback through both material and social mechanisms, which has been shown to support learning (Berland, 2016). Notably, she does so with an embodied relatedness that parents often possess (e.g., sitting closely to share visual perspectives, moving her son with care, and standing directly behind him while looking over his shoulder), which she employs to help choreograph his attention to the spatial relationships relevant for completing his task (Tulbert & Goodwin, 2011).

Episode 3: Sharing a material artifact to understand headings

Winter and her mother are using a compass tool placed around the robot to decide on the appropriate heading value to make it move to their next destination, "a sushi restaurant" (Figure 3a). After Winter assigns the reference heading, her mother asks what heading she chose. We see this question as an invitation for deliberation. Winter examines the compass and responds hesitantly, "Uh zero?" (Figure 3b). In response, her mother provides verbal, tonal, and gestural feedback which implicitly indicates that Winter should reconsider (Figure 3c). To process her mother's feedback, Winter briefly moves her finger counterclockwise along the compass. She then gestures with her hand to the left and asks if the direction she is pointing in is "more like 10" (Figure 3d). Her mother interprets from the response that Winter is still having difficulty estimating the angle adjustments based on a point farther away from the compass. Demonstrating reflexive awareness that her previous explanation using language and gesture was insufficient, Winter's mother pauses to suggest that they "get grandpa's ruler", which she races from room-to-room excitedly to find. This visual representation they construct with material artifacts serves to make the ephemeral radius that they both are referring to a durable representation. With the ruler in place (Figure 3e), Winter's mother sees an opportunity to reset the robot's reference heading to match the heading of their first destination. They coordinate their actions as Winter's mother holds the ruler in place while Winter positions a finger of her right hand in line with it on the compass tool. With her finger held in place marking the spot to which she needs to reset their reference heading, she sets the value (Figure 3f depicts a recreation for clarity). Next, Winter's mother checks for understanding by asking Winter the new value they need to input to reach the destination. Winter quickly responds with a definitive and punctuated "zero", an input that achieves the goal.

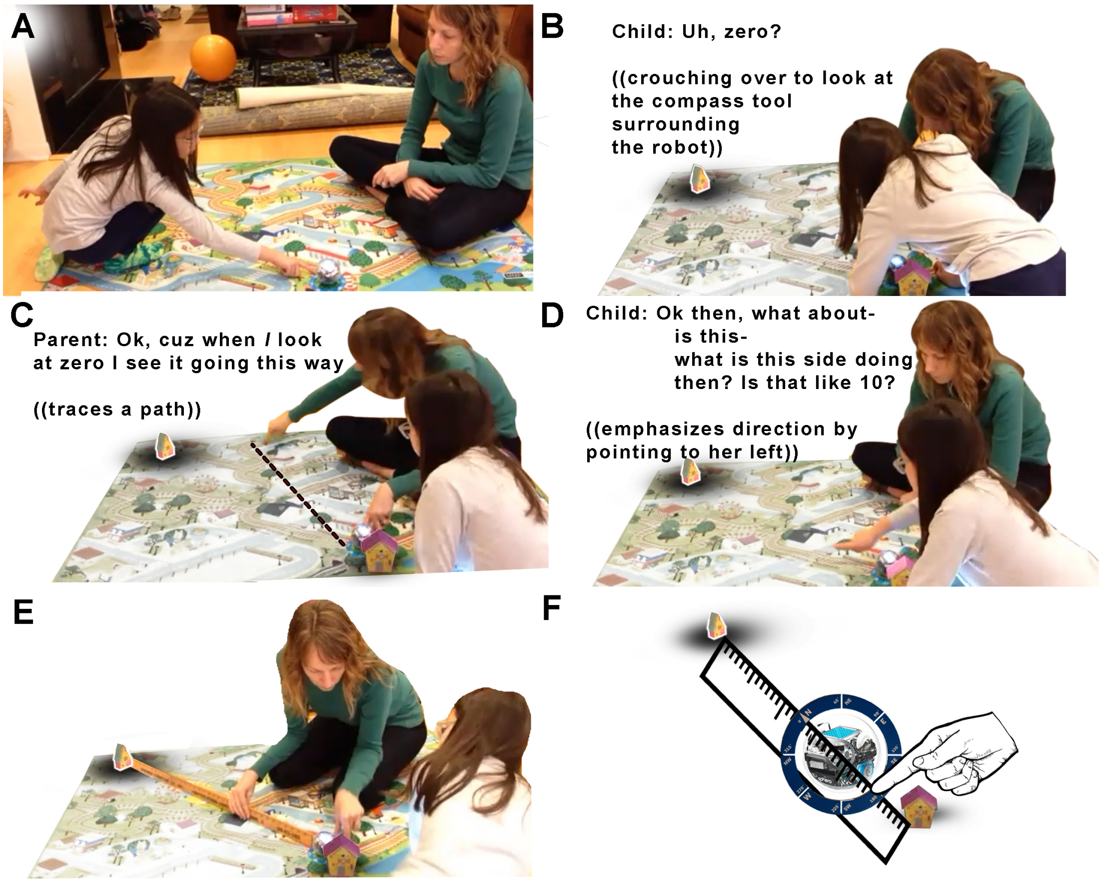

Figure 3. Winter and her mother use a ruler to help with selecting headings.

The ruler placed over the compass is simultaneously a physical representation of their prediction, a tool for greater precision, and an object around which to interact and build further meaning. Accordingly, the mother recruits this everyday object, a tool that is familiar to them both, to generate a locally productive (Hall & Stevens, 2015) flexible learning system (Hike, 1989) in support of the pair's co-construction of knowledge. In this way, they are able to use material artifacts to represent numerical headings (Hutchins, 2005). Winter's mother monitors the physical engagement with this artifact to evaluate Winter's knowledge, the focus of her attention, and the use of this strategy that is meant to help make sense of angles and headings. Staying close to the data only allows us to speculate about the cultural significance of the label "grandpa's ruler." However, the fact that the pair label it as their grandfather's possession, and that Winter exhibits such excitement as she races to various rooms in her house to locate it, indicates how the familiarity and intimacy of objects available in the home may be central to families' practices of constructing visual representations for problem solving.

Discussion and conclusion

This paper described how parents and children make meaning about mathematical and spatial concepts encountered during a playful coding activity at home. In all three cases, children reached moments of impasse during the activity when they grappled with mathematical and spatial concepts. For Landon, this moment surfaced from a need to simultaneously remember and consider information about routes, sequences, and spatial relations. For Alan and Winter, these moments were specific to understanding and manipulating numerical headings. Upon these moments of impasse, all three parents provided critical support that allowed their children to accomplish the coding task at hand. In turn, the pairs were able to continue engaging with the computational aspects of the activity.

Our analysis reveals a theme that parents adapt their communication to shift from verbal to more physical and material representations over the course of meaning making about mathematical and spatial concepts involved in computation with their children. This evolution in modalities emerged as parents closely monitored their children's use of multiple sign systems (Goodwin, 2000), including verbal communication, gestures, and computational input to the programming software. These sign systems served as representations that revealed how children were understanding the content. Parents reflexively responded to this understanding by improvising their communication strategies and recruiting various modalities, such as gestures, embodiment, and the use of material artifacts. In recruiting these resources, parents choreographed their children's bodily movements and directed their children's attention. These behaviors occurred in an intimate and seamless way that is unique and second nature to the parent–child relationship.

Ultimately, this evolution in modalities of communication was critical for the pair's meaning making about the mathematical and spatial concepts that emerged during the coding activity. By recruiting gestures and material artifacts and by coordinating embodiment, parents could reframe and reorient their children's perspectives, while also creating more stable representations of concepts (Hutchins, 2005). This reorientation led the pair to converge their attention on the same system of visual practices and to share the same reference frame. Consequently, the pair achieved intersubjectivity (Goodwin, 2000), allowing them together to establish the use of cognitively opaque cultural tools, such as the compass, and the parent to provide more complete explanations of concepts, phenomena, and practices. In this way, we see parents controlling and constraining parts of the activity that may be too challenging for the children while working alone (Wood et. al., 1976). Although not inherently computational themselves, the mathematical and spatial concepts and computation involved in the coding activity are mutually reinforcing, such that a child's understanding of these concepts supports their abilities to engage in the computation. Thus, this process by which parents reflexively adapt their modalities of communication and direct their child's attention at critical moments demonstrates the invaluable contribution of the meaning making that happens during computational thinking activities between parents and children.

In light of what we see as a dearth of information about how children learn computational thinking skills at home, this research depicts a micro-level analysis documenting the learning process that occurs when children collaborate with a parent on computational tasks. The method we employ offers a granular lens through which we could see the process of collaborative and distributed meaning making during computational tasks and identifies patterns in how this process unfolds. Moreover, our analysis works to account several attributes of the home learning environment, such as the availability of a parent, and acknowledges how this context facilitates parents' and children's abilities to call on familiar material objects, prior knowledge, and social resources that can support their meaning making. Accounts like these not only offer a more fine-grained account of computational meaning making but can incorporate and emphasize more culturally relevant and everyday forms of learning that happen across many contexts, and with many cultural forms (Horn, 2018), tools, and material resources. Therefore, this account represents an important perspective on children's computational thinking and learning at home.

Acknowledgements

We want to express our gratitude to the families who welcomed us (virtually) into their homes for this research. Thanks to fellow students in our lab that offered their assistance, as well as members of our video data club for their thoughtful insights. Also, thanks to our reviewers for contributing helpful comments and suggestions. This work is funded in part by a graduate research grant from The Graduate School at Northwestern.

Bridging the Divide: Exploring Affordances for Interdisciplinary Learning

Vanderbilt University

Abstract: This study investigates how the design of hybrid mathematics and computational activities influences the ways in which students leverage ideas from both disciplinary topics. We examine two design cycles of a computer programming summer camp for middle school students which foreground computational thinking and then mathematics alongside computational thinking respectively. We review the rationale for each design iteration, the trends we saw in students' engagement, and the implications for students' reasoning. Findings of this study demonstrate the importance of thinking critically about the boundary objects that are included in design that support students to make bridges between multiple disciplinary practices.

Introduction

There is significant support for the integration of computational thinking into mathematics classrooms due to content similarities in the domains of computer programming and mathematics (Pérez, 2018; Weintrop et al., 2016). These similarities suggest that learning programming and mathematics simultaneously might be a reasonable way to accomplish a goal of integrating computer science into K-12 classrooms (Harel & Papert, 1990; Gadanidis et al., 2017). However, little research has investigated these claims or, more profoundly, how the synergies between these disciplines might be designed for in such a way that both mathematical thinking and computational thinking would develop. Indeed, bringing two fields together necessarily creates tensions for designers, teachers, and learners; it is these tensions that constitute the focus of this paper. Specifically, we examine two rounds of design in a design-based research project that took two different approaches to support students to leverage mathematical and computational tools with personal agency. We review the design and rationale for each round of implementation, and then consider the implications for students' interdisciplinary reasoning as it is connected to design.

Background and framing

Computer science education is becoming increasingly common in the K-12 curriculum, and educators are adapting to the demand to equip their students with new computational thinking skills (Yadav et al, 2016). This has led teachers and other educational leaders to incorporate computer science through the adjustment or expansion of frameworks, pedagogies, standards, and lessons in the K-12 curriculum (Sentance & Csizmadia, 2016; Yadav et al, 2016).

However, it has been well-established that integrating different learning contexts is neither easy nor straightforward; whether the goal is to connect two disciplines or to connect in-school with out-of-school learning, there is significant evidence that learning is supported and transformed by the norms, tools, and practices of the contexts in which activity is situated (Nasir & Hand, 2008). Central to this idea is that the ways that learning environments are designed (for example, inviting students to think collaboratively one or two open-ended questions versus asking them to work independently on a set of 20 similar questions) fundamentally transforms the nature of what students ultimately learn. An important implication of this work is that "knowledge" is neither static nor abstract but is instead constituted in relation to the learning context (Engle, 2006), and therefore it is no simple or straightforward thing for knowledge to travel between contexts or to connect with new and different knowledge communities (Redish & Kuo, 2015). If learning is truly a *joint accomplishment*, then careful attention needs to be paid both to design and to learning.

How should an activity that invites mathematical and computational thinking be designed? Can one idea be introduced in service of another? Can one set of practices find a home amongst a set of sometimes intersecting but distinctly different practices? To better understand these questions, we draw from work on hybridity, which involves integrating norms and practices from one cultural activity into another. Although there have been many frameworks offered that address hybridity, here we rely on the idea of *boundary crossing* as a lens to examine student activity. As Akkerman & Bakker (2011) write, "A boundary can be seen as a sociocultural difference leading to discontinuity in action or interaction" (p. 133). While the practices and content of mathematics intersect with that of computer programming, there are clear sociocultural differences between the disciplines of mathematics and computer programming. This is especially true with respect to school-based mathematics, the context in which the participants of this study are most familiar with mathematics, which often involves engaging a set of facts and rules to be taught and practiced as an end in itself, in contrast to computer programming which includes design (Kafai, 2016), iteration, and revision. In this work we explore whether and how the particular designs that we undertook served to create bridges between the two disparate worlds of mathematics and programming. Using in-depth analysis of student and teacher discourse, we consider how the boundaries were drawn around these worlds, and how individuals and tools served as boundary objects to connect them. In using this lens, we seek to better understand not whether one design was more successful than another, but rather, how our specific design decisions played out with respect to how different worlds were connected.

Methods

The designs and data presented in this paper come from a larger design-based research study about how student thinking about computation and mathematics might co-develop. Design-Based Research (DBR) is an approach to conducting research with the goal of uncovering why something works and involves testing conjectures and investigating the relationship between activity and outcomes (Sandoval, 2014). As such, DBR is explicitly a theory-building activity, and requires intentional specification of the theories that underlie both initial assumptions and interpretations of data. In particular, theories of how people learn necessarily inform the initial designs undertaken. In contrast to implementation studies that examine whether a particular design is effective, design-based research includes multiple iterations and should specify the changes implied for next rounds of implementation. These cycles of research are a key distinction between understanding why this particular design might function and developing a more nuanced understanding of the relationship between designs and learning more broadly. Thus, the goal of these design iterations is to move beyond understanding what works to consider and be able to account for why it might have worked, with an eye towards not only the success of this design, but the potential success of future designs.

Participant description

The study focuses on the first two rounds of DBR; two free five-day summer camps that were held in two consecutive years. The camps, called *Code Your Art,* were designed for and attended by middle school students and advertised in public middle schools in a medium-sized city in the southern United States. In each year two classes were taught that focused on similar sets of activities; in Year one 30 students enrolled and were split across two classrooms; in Year two 24 students were enrolled and split across two classrooms. Each class was co-caught by two experienced teachers who taught elementary or middle school mathematics during the regular school year. Each classroom was also supported by teaching assistants and researchers who rotated through the classes as needed. The researchers, teachers, and teaching assistants made up the research team that designed and implemented these camps. For this analysis we will focus our interaction analysis on one participant from each year who both consented to all data collection for this study.

Design description

Code Your Art camp introduced students to the ways that a programming environment could produce visual effects and dynamic images. Students used a programming environment called NetLogo (Wilensky, 1999), a multi-agent environment that uses a text-based programming language to manipulate static pixels (patches) and movable agents (turtles). Students were told that by the end of the week their goal was to create a “final design,” which they would share with visitors at a “Gallery Walk” on the final day. Each day students learned a new set of ideas or strategies for creating different visual effects, with the idea that students would use and incorporate those effects that they found relevant to their envisioned design. The explicit stated goal of the research team was for students to see NetLogo as a set of tools that they could use expressively, but how to best position students to think of programming in this way was an open question. One specific question involved whether and how to engage the underlying mathematical ideas that are central to NetLogo, including the coordinate plane, inequalities, number lines, slope, angles, absolute value, distance, quantity and scale.

In Year 1 the design of the camp foregrounded computational thinking, accomplished by offering students a set of NetLogo models that they could explore and modify. Although many of these models involved mathematical ideas, the intentional design of the camp was to engage with underlying mathematical ideas when they were raised by students, such that students’ goals for their own expressive models guided the conversations. In Year 2, based on analyses from Year 1, the design team modified the camp, developing a set of activities that foregrounded mathematics and mathematical connections to NetLogo. Our analysis will focus on how this design iteration changed students' engagement in authoritative problem solving and expressive design in this hybrid math and computational learning space.

Debugging activities

At the end of the third day of Year 1, teachers and researchers designed a set of *debugging models* as an emergent response to significant growth but also some common challenges that students were facing. These models were intended to help students wrestle with and understand the challenges that they were facing as well as see how much they had already learned in NetLogo in order to shift students' ownership of the code.

Each debugging model contained a short description of what should happen in the model if it worked properly; students could read and edit the code embedded in a button in order to fix the "bug." In this analysis, we will focus the first of seven debugging models, *Paint a Square*. The Paint a Square debugging model is a hybrid activity in that its solution requires thinking about mathematics and about programming to create a white square by operating on a set of "patches," squares laid out on a coordinate grid in the model. Changing the color of specific patches requires specifying the patch's x-coordinate (pxcor) and y-coordinate (pycor) using the NetLogo coding language. In Paint a Square, when students clicked the "Setup" button, all of the patches in the window turned blue. When they clicked "make white square in center" a vertical white stripe appeared (Figure 1 Left). The code that produced this effect in Year 1 was "ask patches with [pxcor > 50 and pxcor < 150] [set pcolor white]" which asked all of the patches in the model with an x-coordinate greater than 50 and less than 150 to turn white. Because the window was set up for all students to operate on a coordinate grid with x-coordinates and y-coordinates from 0 to 200, this button colored a white stripe in the middle of the screen. In Year 2 the model was adapted to give directions from the perspective of a client and provide the student with "challenges" rather than a statement about what the model was expected to do (Figure 1 Right). In Year 2 the coordinate plane that is operating behind the NetLogo model ranged from -16 to 16 on both the x and y axis, and therefore the buggy code given to students in Year 2 was "ask patches with [pxcor > -5 and pxcor < 5] [set pcolor white]".

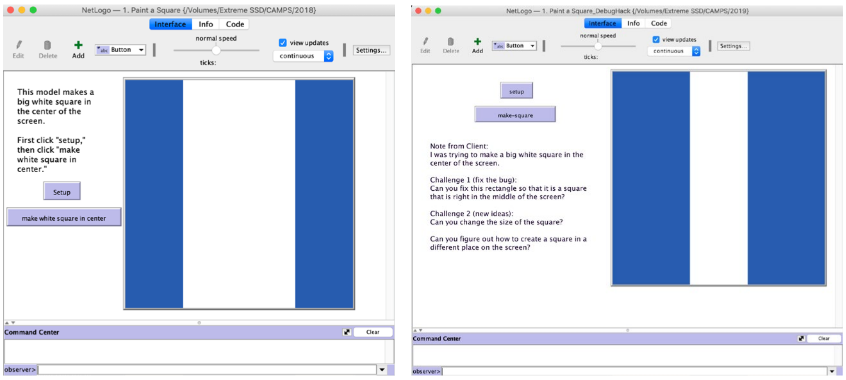

Figure 1. (Left) The Year 1 model after pressing "Setup" and then "make white square in center"; (Right) The Year 2 model after pressing "Setup" and then "make-square."

As stated, we argue that these debugging activities were specifically hybrid activities as "fixing the bugs" required using mathematics within a text-based computer programming activity. To solve this debugging model, students needed to use correct NetLogo syntax, have an understanding of patches as an agent in NetLogo, and use appropriate mathematical concepts such as the coordinate plane. Because of this intersection of mathematics and computational thinking, this set of activities in the camp was ideal to investigate the foregrounding of computational thinking in Year 1 as compared to the foregrounding of mathematics in Year 2. Our analysis will therefore specifically focus on Paint a Square, the first of these seven debugging activities. Because Paint a Square was students' first engagement with debugging this analysis gives a good representation of how the design of the camp and the implementation of the activities that led up to debugging led to differences in how students leveraged ideas from mathematics and computation in the debugging models.

Data collection

Data was collected throughout both camps through whole group video recordings, screen capture video from software installed on every computer, pre- and post-camp written surveys, and interviews. A go-pro was worn by a teacher in each class, a pivoting camera tracked and recorded teacher-student interactions, a standing camera recorded whole group interactions, and individual screen captures recorded individual students' work. Most of the screen-capture videos have a record of both the entire screen and the students face, but on some videos only the screen is visible. The focus of the analysis will be only on the data collected about the foregrounding design and student engagement in the Paint a Square debugging activity described above.

Analysis

Our analysis focused on two aspects of the camp: 1) the ways the designs created opportunities to bridge the disciplines of mathematics and computer science, and 2) how students' engagement bridged the two disciplines, and what designed supports appeared to help make that occur. To make sense of designed opportunities, we reviewed all whole-class activity that took place before the debugging episodes and marked times when mathematics and computational thinking co-occurred. We then considered those episodes, paying attention to when they took place and in what form.

To understand student engagement, we focus on two cases (Brianna from Year 1; Caleb from Year 2), who are representative of the trends in disciplinary approaches to problem solving in the first debugging activity, Paint a Square (Gresalfi et al, 2020), from each of their respective years. These cases represent times when the coordinate plane was operationalized concurrently with the NetLogo code. Using methods of discourse analysis, we looked for times when a participant made connections between the mathematics behind the NetLogo model (such as inequalities and the coordinate plane) and the code that communicates with the NetLogo model. For example, to draw a vertical line at x=-50 and a horizontal line at y=150, one might type "ask patches with [pxcor = -50 and pycor = 150] [set pcolor white]". This code would color a single patch located at the coordinate (-50, 150) white and therefore not reach the goal of the participant, but it would demonstrate that the participant is making a connection between coloring the patches at pxcor = -50 white and coloring the x-coordinates in the model that create a vertical line at x=-50 white. Evidence of bridging math and computer programming holds no matter if the code accurately achieves the mathematical goal in mind. In contrast, if a participant wanted to color a single patch at (-50, 150), they might type "ask patches with [pxcor < -50, 150] [set pcolor white]". This would demonstrate that the participant is not attuning to how the code pxcor relates to the x-coordinate or the relationship of the inequality to the values typed in the code, and therefore not engaging in bridging math and computer programming. These scenarios are also dependent on the context in which the code is typed and include the discourse around the creation of the code.

Findings

In the moment-to-moment interactions between teachers and students, we saw evidence that the different designs in Years 1 and 2 offered different resources that allowed participants to leverage computational and mathematical disciplinary ideas and practices. Specifically, we demonstrate how the Year 1 focus on ensuring that students' work and thinking drove the introduction of new mathematical content meant that there were clear boundaries between the worlds of math and computer programming, that were mainly bridged only by adults who served to broker relationships. In the examples from Year 1, students were reliant on one-on-one interactions with adults to help them connect mathematical ideas with the concepts and syntax of NetLogo. In contrast, the design in Year 2 meant that there were several tools that were provided by adults in anticipation of students needing mathematical connections to NetLogo that appeared to serve as boundary objects to connect the two disciplines. Our analysis of the whole group video data in both years revealed differences in the timing, resources, and motivations behind the opportunities that served as boundary objects for the Paint a Square debugging activity which resulted in changes in the ways in which students leveraged mathematics and computation concurrently.

Opportunities to bridge mathematical and computational thinking

As noted above, in Year 1 the design of the camp approached activities with an explicit goal of open exploration and modification of models in NetLogo. This meant that the underlying mathematics of the models was engaged as students generated a need for those ideas. Therefore, while students did often initiate conversations based around a need for a bridging opportunity between mathematics and NetLogo, it was generally adults who offered information about those bridges, becoming brokers between mathematics and NetLogo. In addition, in Year 1 an designed bridging activity took place on the second day of the camp that asked students to act as patches by holding colored cards and standing on a coordinate grid. The activity introduced a new set of commands that involved patch coordinate location (for example, "Ask patches if [pycor > 1] [set pcolor green]"). Before the commands were given, teachers noted that students were standing on a coordinate plane and each student was assigned a point (for example, 0,1) on which to stand. They engaged in a discussion about how the coordinate plane they were standing on was a limited version of the NetLogo model which was a limited (only positive integers) version of the coordinate plane. In this discussion, teachers also reviewed some basic properties of the coordinate plane. Students then held up various colored cards based on their location in response to NetLogo commands given. We argue that this moment of coordinate plane review offers a bridge between NetLogo and the mathematics of the coordinate plane.

In Year 2, based on analyses from Year 1, the design team modified the camp, developing a set of anticipatory activities that foregrounded mathematics and mathematical connections to NetLogo. For example, on the first day of camp in Year 2 students engaged in a Stadium Card activity similar to Year 1 but were much more explicit about the coordinate plane. Teachers led a whole group discussion that involved every student in the room contributing something they knew about the coordinate plane. At the same time, a researcher modeled students' inputs on the NetLogo model on the projected screen while another teacher drew students' suggestions on a white board. As students gave suggestions, the NetLogo model and white board representation of a coordinate plane were used interchangeably. This allowed students and teachers to bridge traditional school-math language such as words like "quadrant 1" and "x-coordinate" in place of or in conjunction with the NetLogo equivalent such a "top right of the model" or "pxcor." This is just one of four similar bridging activities that took place before debugging. This anticipatory design of utilizing the mathematics allowed for boundary crossing between mathematics and computation to occur collectively rather than in on-on-one interactions as it did in Year 1. The ways in which these boundary crossing opportunities were enacted had repercussions for student engagement and interactions with teachers in each year. We will also note that there were drawbacks to this emphasis on mathematics, as some students' interest in the camp waned that day, which was a noticeable difference from Year 1. We will look more closely at the result of these activities on student engagement through two representative cases from each year.

Year 1 paint a square

Our case in Year 1 focuses on Brianna, age 12, as she learns the connections between her model and the coordinate plane toward the beginning of her work with Paint a Square. At the start of the activity, she overheard a teacher saying that squares are equal on all sides. This led Brianna to change all of the inequality symbols in the code to equal signs and to make four statements in the code saying pxcor = 150, creating a thin vertical white line at x=150. She becomes frustrated and says "Oh, my gosh. I need help." A teacher (T) comes over to the table to check in. In this episode Brianna demonstrates confidence in her ability to use NetLogo as she adds new code and is also attempting to incorporate the mathematical properties of a square into her model.

Code:
```
ask patches with [pxcor = 150 and pxcor = 150 and pxcor = 150 and pxcor = 150] [set pcolor white]
```

1 **T:** How's it going at this table?
2 **Brianna:** Terrible.
3 **T:** Terrible?! You want to talk about it?
4 **Brianna:** Yeah.
5 **T:** Okay, what are you looking at?
6 **Brianna:** I'm trying to turn this into a square but it ain't working.
7 **T:** Okay. What's going on?
8 **Brianna:** I added two more pxcors because there are, because they're supposed to have four equal sides.

Brianna is attempting to utilize her knowledge about both mathematics and NetLogo, as her code is reasonable and her ideas about a square are sound. However, she doesn't yet seem to know how these mathematical properties can be communicated in her NetLogo model; it appears that she believes that "pxcor" relates to the length of the side of the square instead of the x-coordinate of a patch in the model. While it is true that she was attempting to connect mathematics with the NetLogo syntax, this connection was superficial and did not engage with the overlapping content between the code and coordinate grid. To truly hybridize the two, an adult needed to serve as the "boundary object" in the interaction. In this second episode that immediately follows, the teacher reads Brianna's code and assesses her knowledge of this code's connection to the coordinate plane. Based on Brianna's response, the teacher proceeds to teach Brianna about the connections between the code that she has typed, the coordinate plane in the model, and the resulting white stipe that she sees appearing when she runs her model.

11 **T:** *(continues reading code)* "and pxcor = 150 and set pcolor white." Okay, so just this, when it says, "pxcor = 150," where are all the patches with pxcor = 150?
12 **Brianna:** I don't know.
13 **T:** Well, what do they mean? Let's look. Let's hit 'Okay'. (*Brianna runs model)* And if you - oh, no. What happened when you clicked that button?
14 **Brianna:** Just made a skinny line.
15 **T:** It made a skinny line [chuckle]. That's not what you wanted, was it?

16 **Brianna:** No.
17 **T:** No. Awesome. Okay, so where, if I'm looking on the XY plane, where are my X coordinates? Are they horizontal or vertical?
18 **Brianna:** Horizontal.
19 **T:** Horizontal. Awesome. Okay. Where do you think maybe the X coordinate 150 is?
20 **Brianna:** Somewhere over here. (*Gestures to the screen)*
21 **T:** Somewhere over here. Okay. What did you ask the patches to do? Yeah, open that up. (*Right clicks on 'make white square in center' button and opens the edit code tab)* When you say, "Ask patches with pxcor = 150, turn your color white," what are the patches doing? Which ones are turning white?

In line 17 the teacher makes a direct connection to the coordinate plane, and Brianna responds correctly to inquiries about the x-axis (line 18) and the general layout of the coordinate plane in her model (line 20). The teacher then proceeds to help Brianna cross the boundary between mathematics and NetLogo by relating her code "pxcor =150" to the patches on the coordinate plane that she sees turn white in her model (line 21). This line of inquiry and instruction continues between Brianna and the teacher who works one-on-one to connect the NetLogo model and the code used to communicate with it to mathematical concepts needed to solve the problem. Throughout, Brianna communicates to the teacher what she wants to do mathematically in the model and the teacher helps Brianna to understand how to communicate these mathematical concepts to NetLogo. Together, they finalize a model that makes a big white square in the middle of the model.

Brianna's interactions with the teacher were indicative of many students' engagement with Paint a Square in Year 1. It often seemed that they knew how to use the mathematical concepts needed to solve this model, but they are unable to bridge the gap of communicating the mathematics with NetLogo. Therefore, while mathematics and computation are used frequently and concurrently in the debugging models, it is almost always prompted by the mathematical ideas and their connections to the NetLogo code in one-on-one interactions with a teacher. As Akkerman & Bakker (2011) state, "individuals crossing boundaries show how they not only act as bridge between worlds but also simultaneously represent the very division of related worlds" (p. 140). This seems to be the case in examples from Year 1; the boundaries between mathematics and programming remain very clear, and requires the engagement of a broker, in the form of a teacher, to help bring those worlds into contact and conversation. Akkerman & Bakker (2011) characterize this kind of boundary learning as *identification,* which involves "…a process in which previous lines of demarcation between practices are uncertain or destabilized because of …increasing similarities or overlap between practices. The reported processes of identification entail a questioning of the core identity of each of the intersecting sites" (p. 142).

Year 2 paint a square

Our case in Year 2 focuses on Caleb, age 12, during his first attempt on his debugging model. He begins by changing "pxcor < 5" to "pycor < 5" in the original code which changes all the patches in the bottom right corner of the model white. This was a common first attempt in both Year 1 and Year 2. A teacher looks over Caleb's shoulder as he runs his model and engages him in conversation. During the following interaction, Caleb uses some of the school-math vocabulary that was incorporated into the camp by students the day before and uses the concepts from that discussion to create a unique potential solution.

Code 1:
```
ask patches with [pxcor > -5 and pycor < 5] [set pcolor white]
```
1 **Caleb:** Huh
2 **T:** Oh. You got a square but it's just not in the middle
3 **Caleb:** Oh, I see.
4 **T:** He had a square, but it wasn't in the middle. *(directed at another teacher)*
5 **Caleb:** Oh, I know what to do! I know what to do! I know what to do. *(rubs hands together with excitement)*. So, you do, um, you do, you do a square in the first quadrant, second quadrant, third quadrant, fourth quadrant. *(motions in the air to four corners of an imaginary box)* =
6 **T:** = I mean. Okay! Okay! Okay! =
7 **Caleb:** = And it's a square. *(Copy and pastes first line of code three more times and changes each of the inequalities to be either less than or greater than 1 or -1. Runs code to get a smaller white square in the bottom right of the model.)*

Code 2:
```
ask patches with [pxcor > -1 and pycor < 1] [set pcolor white]
ask patches with [pxcor > 1 and pycor < -1] [set pcolor white]
ask patches with [pxcor > -1 and pycor < -1] [set pcolor white]
ask patches with [pxcor > 1 and pycor < 1] [set pcolor white]
```

8 **Caleb:** Wait, what?!

Despite this confusion when getting a square in the corner of his interface when he ran his code (line 1), Caleb quickly assesses this feedback (line 3) and excitedly begins a new strategy, to make one square in each quadrant (line 5) which would come together to make one big square in the middle. His use of the uniquely school-math term “quadrant” as it relates to the coordinate plane in his explanation was common in Year 2 as it referenced the whole group discussion and brainstorming activity that involved identifying the four quadrants of the coordinate plane. With this idea of using quadrants in mind, Caleb replaces all of the numbers in the model to four combinations of 1 and -1, representing the four coordinates closest to the origin in the (line 7 and Code 2). The result is unexpected (line 8). After making a few unsuccessful edits (not shown here but named Code 3 and Code 4) he returns to Code 2 and proceeds with his potential solution.

14 **Caleb:** Oh, I could just delete this. *(deletes all inequalities)*
15 **T:** But you’ve got to have some kind of inequality!
16 **Caleb:** I could just do that. *(Replaces all inequalities with equal signs. Runs code. Gets error due to 1 missing equal sign)* Oh and right here *(types in equal sign)*. Setup. Make Square *(Runs code. Four patches turn white surrounding the origin of the coordinate plane)*

Code 5:

```
ask patches with [pxcor = -1 and pycor = 1] [set pcolor white]
ask patches with [pxcor = 1 and pycor = -1] [set pcolor white]
ask patches with [pxcor = -1 and pycor = -1] [set pcolor white]
ask patches with [pxcor = 1 and pycor = 1] [set pcolor white]
```

17 **Caleb:** *Smiles and looks around to people in his vicinity.*
18 **T:** Ohhhhhh! Okay! Okay! We got 4 squares! *(smiling)* They are -
19 **Caleb:** They are in the middle! *(turns computer to show the people around him)*
20 **T:** You need one square though. That IS kind of awesome.

While, Caleb’s code didn’t initially work because he wasn’t attending to the inequalities in the code, it was apparent from his conversation with the teacher (line 5) that he was attempting to paint the patches located at (-1,1), (1,-1), (-1,-1) and (1,1) white. This is confirmed when he replaces the inequalities with equal signs in Code 5. With his code, Caleb gets 4 small squares that are separated by the points on the x-axis and y-axis of his model which remain the background color of the model. While this isn’t what the “client” in the model asked for, both Caleb and the teachers in the room are impressed and proud of this move toward a solution (lines 17-20). This episode demonstrates Caleb’s use of relevant mathematical concepts based on the whole group discussion about the coordinate plane that preceded the debugging activity, but also his ability to concurrently use those mathematical concepts with the NetLogo code to manipulate the objects that make up the coordinate plane in the model to authoritatively produce an interesting and unique solution alongside but without direct instruction from a teacher.

Caleb demonstrates behavior and interactions with teachers that were typical of his fellow campers in Year 2. Notably, in Year 2, while students still interacted with teachers regularly, the mathematical ideas and the ways to communicate those ideas to NetLogo were largely initiated and pursued by the students. As in Caleb’s case, students often even ignored or corrected teacher’s advice or suggestions, but they did seek assistance when needed to develop new syntax vocabulary or mathematical connections when models didn’t work as expected. Students in Year 2 appeared to demonstrate more authority in their problem solving as a result of having tools necessary to utilize the mathematical content that they knew alongside the computational skills they learned about NetLogo during the camp. This led to more unique solutions to problems and increased ability to develop expressive designs through code.

Conclusion and discussion

In this paper we have focused our analysis on two cases which are examples of the kinds of interactions that we routinely observed in each year of the camp. However, we are mindful that single contrasting case studies are not intended to offer generalizations, and thus we offer a set of conjectures that we feel come out of this analysis. While there are many factors that contributed to differences between students’ experiences in the two years of the Code Your Art camps, the representative cases of hybrid math and computational reasoning that we have explored demonstrates that the design of boundary crossing activities was crucial to students’ engagement in this hybrid learning activity. These bridging activities are ones which enabled students to explore and make connections between multiple disciples. While students in Year 1 successfully completed the Paint a Square activity and did so with high levels of engagement, their success required an expert teacher to broker the connections between mathematics and the computer model in one-on-one interactions, much like we saw in Brianna’s episode. This means that students in Year 1 were constrained in exercising their own agency in exploring different solutions to the debugging problems. Students in both years were certainly productive and knowledgeable of both mathematics and computation, but they demonstrated differences in their agency, problem solving, and expressive designs in the context of debugging. This indicates that the ability to utilize mathematics and NetLogo concurrently is significant to authoritative problem solving in this debugging model. As seen in Year 1, it wasn't enough for students to know the mathematics and to know NetLogo, they had to shift into using both of these disciplines concurrently, which was made more likely to occur independently in Year 2 as a result the implementation of collective boundary crossing activities. Students' engagement with these activities, which elicited relevant mathematical and computational knowledge and skills, demonstrated how both disciplines were connected and could be used concurrently and fluidly to pursue and find unique and interesting solutions to this debugging model.

In order for students to productively engage in learning spaces that require engaging multiple disciplines to solve problems, the designers of those spaces could attune to the areas of intersection between the two disciplines. Preparing students to bridge disciplines requires that the design elicit and demonstrate necessary ideas from each discipline but also demonstrate how these disciplines are connected. As in the Year 2 iteration of the camp outlined in this study, this could come in the form of designing bridge activities within which students can learn to engage in a new form of hybrid participation, one that is neither strictly mathematics nor strictly computer programming. This could offer the potential to develop authority in their problem solving that leads to unique solutions to open problems as the result of the resources available to students based on design. As we see technology and the computer sciences expand into nearly every domain of our global community, the implications for this kind of participation in multidisciplinary learning and problem solving with computers across various disciplines is far reaching and relevant now more than ever.

Abstract: This paper presents findings from a study of elementary teachers participating in professional development (PD) developed to accompany a novel computer science instructional unit. This 7-lesson unit introduces students to programming concepts by having students first play an "unplugged" tabletop board game and then create game levels in Scratch. The PD sessions were structured as a set of participatory routines where the previous week's lesson was reviewed, the upcoming lesson was modeled, and then adaptations to it were discussed. Teacher discourse analyses during PD revealed three kinds of sense-making episodes (reflections, connections, suggestions). Analyses also showed that connection and suggestion episodes were frequently grounded in the board game, matching the intent of the instructional approach for supporting teacher learning. Finally, a majority of the suggestions made by teachers during PD were used during subsequent classroom enactments, indicating teachers' reliance on each other despite their collective lack of experience teaching this content.

Introduction

Elementary level teachers are increasingly being asked to teach computer science (CS) in their classrooms (Blikstein & Moghadam, 2019). However, these teachers often have limited prior knowledge related to CS content, practices, and pedagogy. Teacher professional development (PD) is the typical means for addressing such gaps. Yet evidence on the effectiveness of PD in supporting teacher learning and creating sustainable change in classroom practice is decidedly mixed (Lefstein et al., 2020). This could be because many PD experiences are often in the form of presentations of curriculum and content to teachers rather than opportunities for teachers to reflect and more actively participate in the PD experiences.

In response, new approaches, called collaborative PD, have been developed that invite teachers to be active participants in the process. Examples of activities in such PD approaches for CS include engaging teachers in collaboratively designing (Biddy et al., 2021), modeling (Goode et al., 2014), and reflecting (Yadav et al., 2018) on CS curricula and curricular activities. While these approaches are promising, there is a need to better understand how teachers engage in collaborative PD and the interactions that take place during these kinds of experiences (Walkoe & Luna, 2019). This is especially true for elementary level CS, where little is known about how teachers learn about and teach unfamiliar CS content and curricular activities. Given that the demand for elementary teachers to integrate CS into their instruction is only going to grow, it is important for learning scientists interested in teacher learning to more closely examine teacher PD in this area.

This study attempts to do some of that work. This study is part of a larger design-based implementation research (DBIR) project (Penuel et al., 2011), centered on designing and supporting a CS unit for fifth-grade students. During our second iteration of this design (and the focus of this paper), we were especially interested in the teacher experience of learning, adapting, and enacting this new unit. Our analyses thus focused on teacher discourse during PD experiences to gain insights into how teachers participated, what they learned, and how this influenced their subsequent classroom enactments. Our study was guided by the following research questions: What was the nature of teachers' discursive participation in collaborative PD for this new CS unit? How did collaboration within the PD influence teachers' learning of CS content and pedagogy in ways that influenced their classroom enactments?

Curricular and professional development approaches

The curriculum followed a model for designing CS instruction that we call "Expansively-framed Unplugged" or "EfU" (Lee & Vincent, 2019). The underlying intent of the EfU model is to engage learners with relevant CS content and practices through activities that are personally familiar or accessible and typically do not involve digital technology. These approaches are typically referred to as "unplugged" (Bell et al., 2009). One motivation for using an "unplugged" approach at first is to shift learner's expectations about what one needs to know and understand in order to engage with computing.

EfU is based on the theory of expansive framing (Engle et al., 2012). This theory of transfer posits that making frequent connections back and forth between the context of learning and the context of transfer can help learners create an encompassing context that aids in knowledge transfer. That is, the framing of what kind of activity is being completed is broadened to encompass both the unplugged experience and the digital instantiations (usually in the form of a written computer program).

To enable expansive framing to happen, Engle et al. (2012) identified several specific ways in which connections can be made to help create and strengthen that encompassing context. These include supporting learners in *connecting* settings in order to cue relevant prior knowledge, *understanding* how skills and practice in one setting are useful in a future setting, and *authoring* and *creating* in the new contexts. This model has been used to design more broadly appealing instruction (e.g., Hickey et al., 2020), as well as computational thinking curriculum and assessments (e.g., Grover et al., 2014). In our work, it has been the basis for a design framework for sequences of unplugged-to-plugged CS learning activities (Lee et al., 2020).

Collaborative and participatory professional development

CS represents new territory for elementary teachers to include in their teaching. And while PD has long been used to support teacher learning of new content and curricular approaches, more recent collaborative PD approaches have emerged. These aim to scaffold teachers in engaging in peer discussions, reflecting on the intentions and enactments of new curricula (Borko, 2004; van Es & Sherin, 2008), and developing a shared process for designing and planning adaptations to the lessons to support classroom enactments (e.g., Biddy et al., 2021; Severance et al., 2016; Voogt et al., 2015). These activities offer opportunities for teacher learning as they are closely linked to their everyday experiences and challenges (Putnam & Borko, 2000). Within these collaborative PD approaches, what has been less studied is the *process* of teacher learning during the course of PD engagement; for example, how teachers make connections to their prior knowledge, and how they take ownership of these new ideas in ways that influence their classroom enactments (Walkoe & Luna, 2019).

Although EfU was intended as a situated approach to support student learning and transfer, we posit that it also applies to teachers with little CS and programming background by helping them, like their students, make connections from their prior knowledge to new CS content. Unlike the other topics they may teach, elementary teachers are often also learners in the CS content area, and the EfU model designed for students may benefit teachers as well. Thus, we posit that designing a CS curriculum informed by unplugged ideas and expansive framing will lead to activities with low threshold for *both* teachers and learners. Further, when the accompanying PD is supportive and collaborative, it will help teachers with little computer science background successfully engage with, adapt, lead, and support such activities. We next describe a study to examine these conjectures.

Methods

Setting and participants

The project was oriented as design-based implementation research (Penuel et al., 2011). Specifically, we worked with a local school district to address a problem of practice (offering CS education at the elementary level), to commit to iterative design (implementing in different schools), to contribute to theory (examining design implications of EfU for students and teachers), and to design for sustainable change (involving teachers in collaborative PD).

To address this problem of practice, we designed a new instructional unit that could accommodate the time constraints faced by teachers. We also deliberately involved school library time and school librarians as per the partnering district's request. As discussed elsewhere, librarians, and school librarians in particular are beginning to take on some of the role of providing CS learning opportunities for their library patrons (Lee et al., 2020). We worked closely with two rural elementary schools, one each year over two years. For the current study, we focus on the second iteration, involving three fifth-grade teachers (Maria, Teresa, and Debbie; all names are pseudonyms), one teacher librarian (Julia). The fifth-grade classes enrolled 74 students.

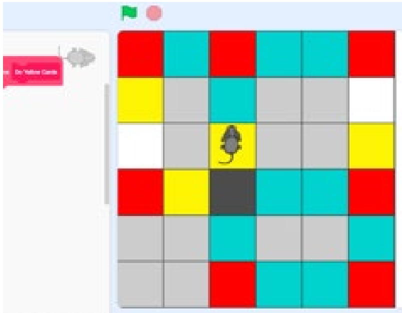
Expansively-framed unplugged CS curriculum

Following the EfU model, we designed a seven-lesson CS curricular unit to fit within teacher and librarian allotted time for this unit. The initial draft of the scope and sequence of the unit was sketched at a high level by the researchers with the intention of using the collaborative PD sessions (described below) as a space for teachers and the librarian to propose adaptations for their specific school context.

In this unit, students first play an unplugged tabletop board game, *//Code: On the Brink* (see Figure 1) which, as a game, may be more broadly appealing while also serving as a rich space to explore several computing concepts. Students then play a digital version of the same board game programmed in the block-based programming language, Scratch (see Figure 2). Finally, students create and program their own game levels and challenge other students to play them.

The lessons were designed to span both the classroom (preparatory lessons introducing CS concepts) and school library (playing the board game and programming the digital version of the game). Game playing was situated in the school library because it aligned with the partnering district goals, and, as found in prior research, board games were a common library activity for students in the district (Lee et al., 2020). Classroom and library enactments for a lesson each lasted approximately 20 to 30 minutes.

Table 1 shows an overview of how the unit unfolded across lessons and classroom and library settings, and the specific CS concepts addressed. Specific lessons also highlighted EfU phases, including connecting to prior knowledge (lessons 1-3), connecting between settings (lessons 3-6), and authoring (lessons 6-7).



Figures 1 & 2: Sample Levels from *//Code: On the Brink* tabletop board game and Scratch version

Collaborative professional development: structure and routines

The three classroom teachers, teacher librarian, and two researchers participated in weekly 45-minute collaborative PD sessions that preceded each of the seven lesson's enactment. Each PD session was structured to follow a set of participatory routines: 1) reviewing the previous lesson's enactment, with a focus on noticing equitable student participation and engagement, 2) modeling the current lesson, 3) discussing the lesson and related CS concepts, 4) discussing adaptions to the lesson plan, and 4) revising the lesson plan based on that day's discussions. All lessons plans were developed using Google Docs to support easy modifications and commenting by researchers and teachers alike.

In the first three PD sessions, a researcher modeled the lesson while the teachers acted as classroom learners, thereby using a "teacher-as-learner" modeling approach where teachers engage in the unit as students (Goode et al., 2014). In the final four PD sessions, each teacher took a turn leading the lesson while the others acted as students. Note that not all teachers were able to attend all PD sessions.

Table 1: Focus of each PD session and accompanying classroom and library lessons

	Lessons 1-3	**Lessons 4-6**	**Lessons 6-7**
Classroom	Learn about conditionals and step-by-step programming	Learn about conditionals, procedures & how to program in Scratch	Review CS concepts in the game
School Library	Play board game and Scratch versions of game	Design and program own game levels	Play each other's games
CS concepts	Conditionals, algorithms, procedures	Conditionals, debugging, simulation, abstraction	Review
EfU phases	Connect board game play and prior knowledge	Understand how board game play informs game design and programming	Author (program) new game levels

Data sources and analyses

Audio recordings of the seven PD sessions and classroom enactments for all three teachers were transcribed and then inductively coded, categorizing utterances by their conversational purpose (e.g., reflection) as well as content (e.g., pedagogy). Talk unrelated to the curricular unit was not coded (e.g., "I have bus duty so we need to shift the meeting time"). Among the conversational purposes coded were *suggestion*, *reflection*, and making a *connection*.

Once utterances were coded for purpose and content, we noted that the discourse typically consisted of extended collaborative discussions. These were coded into episodes called *suggestion*, *connection*, and *reflection*, or collectively, *sense-making* episodes. These episodes framed much of the meaningful conversation that occurred during the PD, and, in what follows, we describe these episodes to provide context for the findings that they frame.

The sense-making episodes consisted of at least one of the three types of utterances, as well as a *triggering event* that caused the utterance to be made. This would often take the form of the first part of an adjacency pair (Schegloff & Sacks, 1973), such as a peer's question. The focal utterance (i.e., suggestion, connection, or reflection) would be the second half of the adjacency pair. Then we examined the "trailing" conversation that occurred after the utterance was made. This tended to contain concurrences or clarifications from other participants. The episodes were bounded by the presence of the adjacency pair or statement of a new topic. All utterances coded as suggestion, reflection, and connection were included in episodes, although some were grouped into the same episode if they focused on the same conversational topic and occurred close to one another. This would happen, for example, when two teachers would make suggestions in response to the same question.

After identifying these sense-making episodes, they were coded to determine their topic and the type of triggering event for each. We also analyzed them for various other features, such as length, placement within the PD, and the type of utterances that occurred in the trailing conversation. Finally, after identifying all episodes, we looked for evidence of the use of a suggestion or connection made during the episodes that translated to the classroom by reviewing the classroom enactment transcripts.

Findings

Overall, we found increasing teacher participation in the PD over the course of the 45-minute PD sessions. Figure 3 shows how the number of sense-making episodes grew over the seven sessions, with a 60% increase in the number of episodes in the final three sessions as compared to the first four. In those final three sessions, the teachers, rather than the researchers, were modeling the lessons.

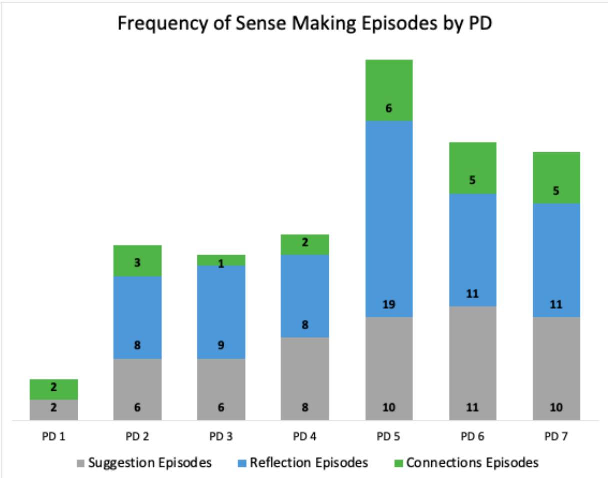


Figure 3: Frequency of sense-making episodes over PD sessions

We found that conversations during suggestion and connection episodes in particular were important in affecting the ways that teachers made sense of CS ideas. We next describe these two types of episodes in more detail and illustrate how they affected teachers' pedagogical choices during classroom enactments.

Suggestion episodes

Suggestion episodes occurred when teachers recommended changes to the lesson plans for the CS unit. While some of the episodes contained only one suggestion made by a single teacher, many contained multiple suggestions made by multiple teachers as they engaged in conversation about a particular topic, such as how to teach the concept of a procedure to students.

In the following example suggestion episode, Maria, a teacher, is modeling the upcoming lesson where game cards specify moves (e.g., hop forward) made by the game piece (a sprite) and acting as if she were talking to her students (Macey and Jacob):

Maria: So, if you made your own card, like 'I know, Macey [a student], you did a hop forward', 'I don't know what hop forward means'. 'I'm the sprite, so you're gonna have to tell me'. So, we're gonna have to make our own procedures right here for what it means to hop forward.

Julia (Librarian): Well, it means 'just hop forward', is what they [the students] said to me.

Maria: ‘Okay, Macey, what does the hop, hop forward mean to you, think it in your head’. ‘Jacob, what does it mean?’ ‘Ok, what does it mean, Macey’, she tells me, ‘Jacob [a student] tell me.’ ‘Oh, so like this, or like this?’ (*Maria hops twice)*. ‘Which one? Who's right? How do I know?’

Debbie: Okay, that works.

Here we see Julia, the librarian, make a comment about what students have said to her in the past and therefore how they would likely respond. Taking this into account, Maria then incorporates the suggestion seamlessly into her modeling of the lesson, showing how the teacher can have students demonstrate their personal definitions of a procedure to show the importance of procedural precision.

Over the seven PD sessions, teachers generated a total of 53 suggestion episodes (see Figure 3). Further, teachers made 41% more suggestion episodes during the final three PD sessions, when the format of the PD was more teacher-led. Suggestion episodes covered a variety of topics—the use of Scratch, general pedagogy, and CS-specific pedagogy. In particular, 41 (77%) of these suggestions were pedagogical in nature, with half of those being specifically related to CS pedagogy.

Finally, we note that peer questions and peer reflections triggered a majority of the suggestion episodes, accounting for 36 of the 53 (70%). This is indicative of the value of teacher-led conversations and peer collaboration in helping teachers develop agency in recommending adaptations to the lessons. This claim is further supported by the fact that 10 additional suggestions were made when teachers were modeling upcoming lessons—a component of the PD that was teacher-centered and teacher-led.

Connection episodes

Connection episodes illustrate how teachers make connections between the CS content and other content. The connections focused on their growing understanding of programming and the Scratch interface, and often drew on past experiences, prior understandings, and the board game used to frame the unit. In the following example, teachers are discussing the concept of programming abstraction and are beginning to differentiate between procedures and abstraction:

Maria: I mean, I don't think I knew the word abstraction.

Teresa: The kind of all, I mean, is like, well, the procedure isn't a small abstraction.

Maria: Yeah, maybe I was actually like, so procedure was like all the steps, right? And abstraction is like the act of doing it. Maybe I wasn't, I don't know if I taught that completely correctly.

Teresa: You could have really big abstractions—

Maria: Well, cuz like I said, like I gave a similar example about the sharpened pencil like, when I say get out your Elevate [district curriculum] stuff, we know that means get out this, this, this, start your language sheets, like you don't have to say all those steps.

Teresa: Right.

Maria: So, I kind of said that, but—

Teresa: Yeah, and the algorithms are all the instruction—

Maria: And those are the procedures, the abstraction is like the act of making it smaller?

Researcher: Yeah.

Here, the teachers connect the concepts to their classroom teaching and use “Elevate”, the district-authored writing curriculum, as an analogy to explain their thinking.

Many of the connection episodes consisted of analogies meant to help relate the content to every-day occurrences, like the weather or classroom routines. Furthermore, half of the connection episodes involved comparing CS content to the board game, suggesting the value of the expansive framing instructional approach. One example of such an episode occurred during the second PD session, when teachers were trying to make sense of the definition of CS events and turned to the board game’s rules to define the meaning of the term:

Researcher: So, level 15 would be right here. Okay. Right. And so, looking at level 15, we would say what are some of the events that you see? And there's two ways to answer this, right? One of this we could say, actually, we'll just have you guys, what are the events that are on here?

Maria: I think as a kid, I would be like, ‘wait what do you mean, like what—'

Julia: Yeah, I wouldn't understand what the word events means either. […]

Debbie: Well, if it's, like what you're saying with the games, are you meaning like when I land here, I need to turn left, is that what you're wanting as an event? […]

Teresa: Or this guy has to turn right or left before he—

Maria: Yeah, they're gonna start telling you what to do, I think. […]

Debbie: And is that considered an event?

Researcher: Yeah, I mean, that would be an event, and probably what I would consider is that if you're on red, do the red cards.

Maria: So, landing on red is, or being on red is the event.

Researcher: Yeah. So being on red is the event.

As seen in this episode, teachers used the board game mechanics of determining movements based on the color that the sprite is touching (“being on red”) to understand the meaning of a computational event. Across all PD sessions, teachers generated a total of 24 connection episodes (see Figure 3). While the number of connection episodes was lower than other sense-making episodes, they almost doubled during the final three PD sessions—again, sessions which were more teacher-led.

Classroom enactments

We examined the three types of episodes to see how the collaboration within the PD influenced teachers' classroom enactments. First, connection episodes impacted the way that teachers described CS content to their students. An example of this was the enactment of the previous excerpt, where all three teachers explained events or conditionals using the game mechanic of how touching different colors caused the sprite to perform different moves.

Second, we also found that suggestion episodes influenced teachers' CS pedagogical enactments. Of the 53 suggestion episodes that occurred during the PD sessions, 33 had the potential to be used by teachers in future lesson enactments. Of those suggestions, 23 (about 70%) were enacted by at least one teacher, 14 (42%) were enacted by two of the three teachers, and 10 (30%) were enacted by all three teachers.

For example, a suggestion that was enacted by all three teachers was to have students physically stand up and move their bodies to demonstrate new game procedures during lesson 3. This was used by each teacher but enacted in slightly different ways. Maria had one student stand and demonstrate the new procedure, Teresa had all the students do it simultaneously, and Debbie had students individually demonstrate procedures before having the whole class do it together. The use of an idea that was not in the lesson plan and the varying ways in which teachers took ownership of the pedagogical choice shows their agency in classroom practices as well as their engagement in the PD.

Figure 4 shows the flow of suggestions between teachers, with the arrow pointing from the teacher who made the suggestion to the teacher who used it. A circular arrow represents a teacher enacting her own suggestion. As can be seen, each teacher relied on suggestions made by peers, as well as a smaller number of suggestions made by the librarian.

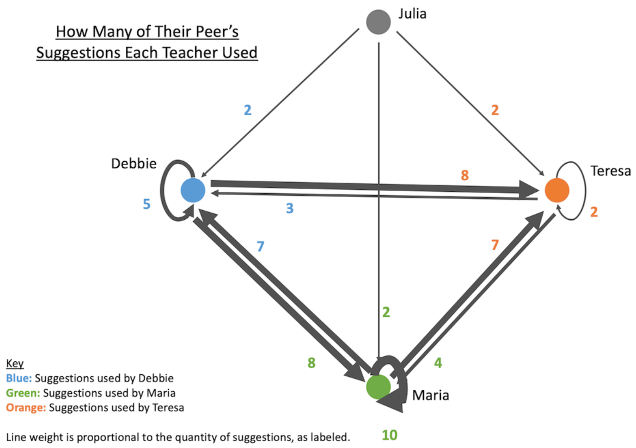

Figure 4: How teachers enacted peer suggestions (circular arrows represent a teacher taking her own suggestion)

Figure 5 shows the percent of topics of suggestions enacted by teachers in their classrooms. Suggestions regarding CS-specific pedagogy were taken up the most by all three teachers, as would be expected given the unfamiliarity of the CS content. In particular, 12 out of 16 (75%), of all CS pedagogical suggestions were used by at least one teacher. Thus, teachers appeared to rely on each other to find enactment advice, despite their collective lack of experience in the subject matter.

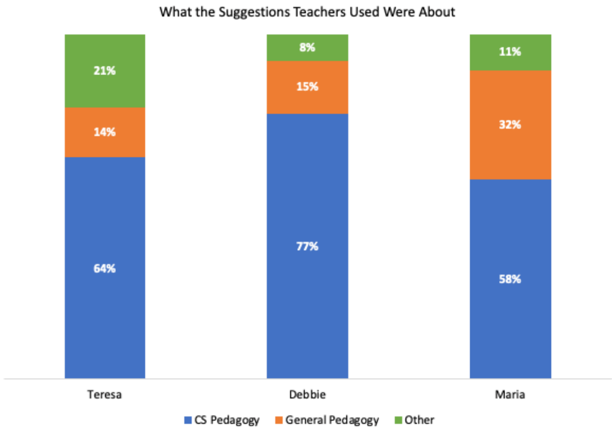

Figure 5: Topics of suggestions enacted by each teacher

Finally, teachers also used a large proportion of suggestions that occurred during lesson modeling. In particular, 91% came from the modeling portion of the PD or the conversation immediately following their modeling, where teachers were still discussing their plans for the upcoming lesson. While modeling activities did take up more time and therefore were more likely to generate suggestions, the highest percentage of the suggestions made during the modeling portion —which was more teacher-centered and directed—were enacted than from any other PD activities.

Discussion

This paper investigated how elementary teachers participated in a collaborative PD for a 7-lesson unit that was new to them both in content (CS) and pedagogy (EfU). The PD sessions were structured as a set of participatory routines where teachers reflected on the previous week's lesson, modeled the upcoming lesson, and discussed adaptations to it. While these kinds of routines have been incorporated in other PD designs, our study closely examined teachers' utterances to characterize the kinds of sense-making episodes they engaged in during the PD sessions. We identified three episode types and found that episode frequency increased over the course of the PD sessions as teachers gained agency in the PD process.

By closely analyzing the specific episode types, we unpacked how teachers participated in the PD, what they learned, and how these interactions influenced their classroom enactments. The connection episodes showed how teachers made connections between their teaching and the content as well as between the board game and the content. While the EfU approach is intended to support student sense-making, the findings suggest it also supported teachers' sense-making. Further, the vast majority of suggestion episodes, where teachers recommended adaptations to the lessons, were pedagogical in nature, with half of those being related to the specific CS pedagogy. Our findings thus show how the teachers developed a repertoire for teaching CS despite its relative unfamiliarity and, like previous work, show how teacher agency during PD can lead to curricular changes (Severance et al., 2016; Voogt et al., 2015).

Conclusion

Elementary teachers with little CS background are increasingly being asked to include CS in their instruction. To help prepare teachers for this, learning scientists need to better understand the process of teacher learning in order to design impactful PD. In this paper, we examined how teachers in our study actively made connections and took ownership in suggesting adaptations to the curriculum in ways that influenced their classroom enactments.

DBIR approaches can be powerful ways to address local and meaningful problems. Nonetheless, questions remain about their scalability and sustainability. The study highlighted several routines, tools, and strategies to structure collaborative PD that appeared to result in fruitful teacher engagement and agency in lesson enactments. Future work should examine to what extent these can be productively employed in other PD settings without researcher support. Further, the content in the current study only addressed introductory CS ideas—engaging teachers around advanced CS concepts might be harder to realize in this setting.

The Tragedy of Lost Ideas: Examining Epistemic Injustice in Pair Programming

Abstract: This paper explores an episode of epistemic injustice that develops between two students with help from two teachers. Our analysis seeks to demonstrate not only *that* epistemic injustice has occurred, but also, how, and why it matters. In particular, we explore the idea of credibility deficit as helping to account for how and why one student's contributions were routinely sidelined or ignored, and how that repeated positioning led to the ultimate act of testimonial injustice and its outcome, a wrong in the form of a loss of opportunity to learn.

Introduction and framing: Situating the problem

Despite the many calls and enthusiasm for "equity-oriented" instruction, it continues to be true that American schools are generally organized in an unsafe manner for students of non-dominant cultures to learn, engage, and thrive (Dumas, 2014; Martin, 2019; Ryoo et al, 2020). This is particularly true in STEM, where success is often associated with overall smartness (Leyva, 2017). At the same time, STEM fields often contribute to and are organized by persistent structural racism seen both in instructional practices and in the ways that resources and opportunities are made available to some students but not others. Combined, this ensures that only some students are recognized as successful, and that those who are denied such recognition are doubly damaged by narratives that claim failure in STEM to be central to overall failure.

This well-documented situation is often the focus of research and reform efforts. However, as Martin (2019) has pointed out, the extent to which such reform efforts engage beyond a surface-level concern with test scores vary widely. Efforts to transform education must take broader institutional and instructional practices seriously, for without such attention, the very same patterns that lead to inequities can flourish (Ryoo et al 2020). Reforms should focus not on how to ensure that students are successful within existing structures, but rather, should ask how existing structures should be transformed to promote success. As Ryoo et al (2020) say: "CS education should not simply thrust minoritized students toward status quo and middle-class ideas of working as uncritical programmers, but instead encourage students to utilize their diverse lived experiences and voices to ask the critical question: computing *toward what ends?*" (p. 339). Without focus on transforming these structures, classroom spaces continue to be unsafe for some students; without attention to students' interaction, broader narratives about success and status permeate interactions.

Care about others' humanity should be sufficient justification to ensure that classrooms and schools—sites of mandatory participation—are both safe and sustaining for students. But in addition, it has been well established that our experiences drive the identities that we develop—how we participate and learn, what we believe about ourselves, and what decisions we make about our future (Nasir & Cooks, 2009). Thus, the ways we organize classrooms have implications not only for the moment, for the year, but for a lifetime.

In this paper, we examine a 45-minute interaction between two boys, one Black and one white, who are working on an open-ended programming challenge that requires both mathematical and computational thinking. In our analysis, we ask how the relationship between two pair programmers changed dramatically over the course of a 45-minute episode, leading to an outcome of *epistemic injustice*. Specifically, we ask: How did the interactions between two students serve to systematically position an older and more knowledgeable student as less competent? And what are the implications for identity development and learning?

Conceptual framework

To conceptualize the unsafe nature of STEM environments for minoritized students, we draw on Miranda Fricker's concept of *epistemic injustice*. According to Fricker (2007), epistemic injustice is harm done to someone as a knower due to their identity. Identity markers, such as race, gender, class, or accent can increase or decrease trust that a person knows a certain type of information. Although there is more than one form of epistemic injustice, here we focus on *testimonial injustice*, when a knower tries to convey knowledge, or give testimony, but is not seen as credible. Certain identities in certain contexts can create a *credibility excess* or *credibility deficit*, where a speaker's word is either unfairly inflated or deflated due to who the speaker is. Fricker also highlights the many wrongs of testimonial injustice. First, to be wronged as a knower is an intrinsic injustice because it undermines a person's worth, identity, and capacity to reason. Not only is undermining a person as a knower often hurtful, but further, as Fricker states, "[I]n contexts of oppression the powerful will be sure to undermine the powerless in just that capacity, for it provides a direct route to undermining them in their very humanity," (p. 44). In addition, persistent undermining will cause a knower to lose confidence in what they believe and why they believe it, which results in the knower literally losing knowledge. And finally, such prejudice can have a self-fulfilling power that can cause the person subject to the prejudice to start to believe and behave as if such prejudice is true. Overall, testimonial injustice is one of the ways that we can understand why some people are systematically ignored, dismissed, or undermined in interaction, and what repeated instances of this injustice can do over time. In this paper, we will show the ways in which one student subject to testimonial injustice not only conceded to the prejudice he was subject to, but in the process lost knowledge.

Although epistemic injustice is largely a philosophical concept in its origin, it has a clear utility in studies of learning and interaction. For example, Miller et al. (2018) state that epistemic injustice is highly relevant to the context of implementing Next Generation Science Standards (NGSS). Specifically, they argue that if minoritized learners are not granted epistemic agency in science, not only will they lose confidence in themselves as knowers, but there will be a net-loss in the science community due to the lack of opportunities for these groups to foreground their knowledge and shift our collective scientific understandings (Miller et al., 2018). In mathematics, Tanswell and Rittberg (2020) critique a norm of mathematical practice that presents mathematics as acontextual. Further, university math programs often use a streaming model to weed out lower performing students, which diminishes the social aspects of mathematics (Tanswell & Rittberg, 2020) and instead promotes an individualistic, competitive environment, which runs contrary to many minoritized communities that value collectivism (Bills & Hunter, 2015). Hunter et al. (2016) show that when students are allowed to make sense of math by communicating in a shared language, students can mathematically reason at an advanced level, but students rarely receive the opportunity due to the credibility excess of the English mathematical vernacular. Since human learning is inherently contextual (Lave & Wenger, 1991), any practice that ignores the context of the learner is a source of epistemic injustice (Tanswell & Rittberg, 2020). Building on these efforts to investigate and understand how interactions between students in learning contexts establish epistemic injustice, our analysis explores moments in which credibility deficits are established, with what we argue to be an ultimate outcome of epistemic injustice.

Methods

We use interaction analysis (Jordan & Henderson, 1995) and positioning theory (Harre & van Langenhove, 1999; Anderson, 2009), to explore a 45-minute episode of pair programming in which two boys were engaged in a debugging activity. Details about the data, the activity, and the analytic methods employed are detailed below.

Data

The episode comes from the second day of a week-long free coding camp called *Code Your Art,* which introduced middle-school students to coding through NetLogo (Tisue & Wilensky, 1999). The students were engaged in a pair programming debugging task called "Paint a White Square" which called for students to modify "buggy" lines of code that resulted in a blue background with a white strip down the middle, rather than a white square (Figure 1). Modifying the code to create the correct image required thinking about the syntax and logic of NetLogo, as well as mathematical properties relevant to the model. However, there were many possible solutions to debugging this model that resulted in a display of a white square in the middle of the screen. After creating the white square, students had two challenge problems: to create a white square of a different size, and to create a white square somewhere else on the screen.

The specific data that we analyze for this piece comes from screencapture software from one boy (Sam's) computer, which was passed back and forth between the pair. The screencapture software includes both what is happening on the screen and the video that is captured by the embedded computer camera. This meant that whoever was typing on the computer was directly captured by the embedded computer camera, and often both students' faces were seen on the computer camera, particularly when they were both leaning in to look at the screen. The two students who are the focus of the analysis are Prince, a Black rising 9th grader, and Sam, a white rising 6th grader. Their partnership was based on their proximity of seating in the class, and the two boys had no prior relationship before the summer camp. Our analysis also includes the task that students were working on, and the adults who interacted with the pair, including Victor, a white male undergraduate teaching assistant (TA), and the lead teacher Ms. Turner, a Black female math teacher with over 20 years of teaching experience. The exercise lasted about 45 minutes.

Analytic framework

The analytic methods that we brought to bear on this episode come from principles of interaction analysis and from positioning theory. Interaction analysis (Jordan & Henderson, 1995) is a method of video analysis that draws a unit of analysis around the person and their context. Interaction analysis assumes that "knowledge and action are fundamentally social in origin, organization, and use, and are situated in particular social and material ecologies" (p. 41). This means that analyses must take seriously not only what individuals do, but also, how their participation is shaped by and responsive to the actions and affordances of other people, tools, and practices. Following these practices, our analysis began with repeated viewings of the 45-minute episode, followed by creation of a content log of the entire interaction. These initial viewings helped to make us aware of a shift in participation that we found both puzzling and troubling; what began as an apparently cordial and relatively cooperative activity shifted over time with one student becoming increasingly silent. We thus decided to look in detail at the interaction between the two students to try to better understand what happened.

For our closer analysis, we drew on positioning theory (Harre & van Langenhove, 1999; Anderson, 2009). Positioning takes place at two levels--as a moment-by-moment process through which people make bids for and establish their relative status, and in relation to broader narrative and storylines, which are both implicitly and explicitly leveraged as resources to situate particular discourse moves (Hand, Penuel, & Gutierrez, 2012). At the moment-by-moment level, positioning can be seen most easily in talk, as students and the teacher speak to each other about academic content, about themselves, and about their current work (van Langenhove & Harre, 1999). When looking over longer time periods, students can be positioned as being certain kinds of people in relation to broader storylines that are made relevant through the emergent participant framework (Goffman, 1974; Goodwin, 1990; Herrenkohl & Guerra, 1998; O'Connor & Michaels, 1996) of a classroom which shapes the ways that students are expected, obligated, and entitled to participate with content and with others in the classroom.

Findings

Figure 2 offers an overview of the content of the 45-minute episode between Sam and Prince. From the outset of the episode Prince and Sam demonstrated active engagement in the white square debugging task, as they took turns analyzing the problem presented and determining potential solutions to pursue during the first phase of problem solving. However, their first interactions with the code were generally cooperative, rather than collaborative. For example, Sam first independently explored the model and attempted two common solutions that involved changing specific symbols and numbers in the code. When those initial strategies didn't work, he rotated the laptop towards Prince and said "here, you try." Prince did so, and ultimately proposed a different strategy after exploring the model himself. As we detail below, while the content of their conversation focused on programming solutions, the interactions between the boys also served to establish their relative status. This positioning began through interactions between the two boys, and then was reinforced through interactions with the TA (Victor) and the lead teacher (Ms. Turner). Close analysis of these interactions suggests that Prince was repeatedly positioned as a non-knower. However, Prince's response over time shifted noticeably from first strongly rejecting those bids, to quietly not contesting them, to finally verbally acknowledging them. We unpack these interactions that, we argue, establish Prince's *credibility deficit in the interactions*, leading to an overall experience of testimonial injustice, and harm to Prince's identity as a knower.

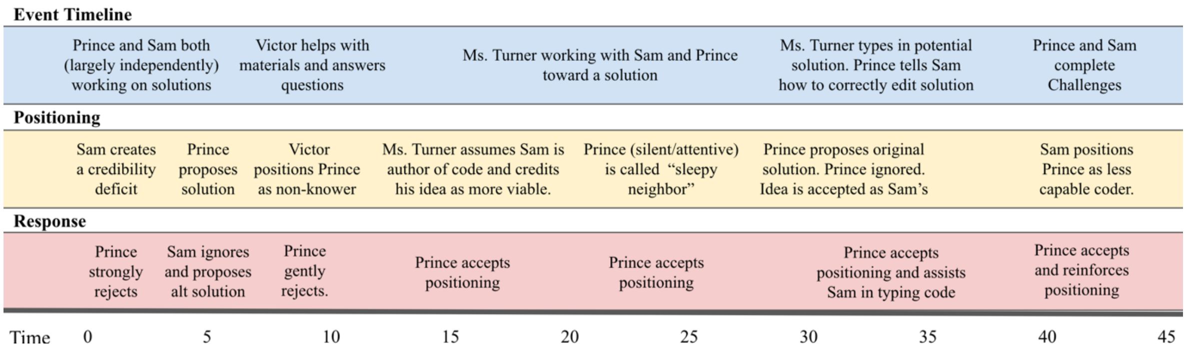

Figure 2. Overview of the 45-minute episode between Prince and Sam.

Phase 1: Positioning rejected

From the outset of their interaction, Sam positioned Prince as non-essential to the task. This happened first, subtly, when Sam ignored Prince's attempt to help him open the model, and subsequently, by Sam's initial attempt solve the White Square problem independently. These moves suggest that Sam anticipated Prince's ideas not being worthwhile (or, at the very least, that Sam did not need any assistance to solve the problem, despite being asked to work in pairs). This positioning was made more explicit when Prince was given access to the computer and made his first bid to solve the problem, an interaction in which Sam more explicitly claimed Prince's contributions as unworthy. This is seen in the transcript below, which occurred approximately 5 minutes into the video.

1	Prince (P):	Are we gonna make a square right here or right here (*pointing mouse to top right and bottom right corners of the NetLogo interface)*
2	Sam (S):	In the middle
3	P:	In the middle...
4	S:	Yeah
5	P:	We already have this (*clicks on white strip in the middle of the screen*)
6	S:	I know and now we need to just go chop, chop, take away, take away...
7	P:	Oh, it's a big *white* square
8	S:	Yeah, and then try to change the size of the square.
9	P:	So... we gotta do something with the pycor.
10	S:	You think???
11	P:	No sir, I did not think. That was all muscle memory. So... we just go down... (*begins typing new line of code*)
12	S:	Screw everything up

In turns 1-8 Prince explored the model for the first time. In turn 9, Prince made a bid for how to address the bug, focusing on an aspect of the code that is currently missing (the code in its initial state reads: "ask patches with [pxcor > -5 and pxcor < 5] [set pcolor white]"). Prince's proposal was an unusual one for students to offer at the onset of working on this problem (c.f. Gresalfi, Brady, Knowe, & Steinberg, 2020), but is a necessary path towards a solution. It was also not a solution that Sam had explicitly tried in his earlier testing of the model. However, in turn 10 Sam responded to Prince's proposal with a dismissive "You think?" In this move, Sam positioned Prince's contribution as obvious and uninteresting, offering the first assertion of Prince's *credibility deficit.* However, Prince rejected this positioning in turn 11 almost without pause, claiming that he didn't even *have* to think. Still, as he began to add a new line of code to address the y-coordinates, Sam quietly muttered "screw everything up" suggesting a lack of trust for Prince to derive the correct solution.

As Prince began to type, Sam began to work independently on his own idea, seen in turns 15-19. His lack of attention to Prince further positions Prince's ideas as unworthy in Sam's eyes. Although Prince appeared to be aware of Sam's movements and his lack of attention (for example, Prince leaned back when Sam reached in front of him but did not look away from the screen where he was typing), he did not object to or engage in any way with Sam's utterances, again serving as a rejection of Sam's positioning of his ideas as unworthy.

15	P:	Oh, I got something... ask patches, ask patches...
16	S:	(*talking over Prince*) I wish we had something we could write this down on. We never got one of those dry-erase things to write on.
17	Victor (V):	Yeah you do, he has it (*alluding to Prince having a dry-erase board*). You have to share.
18	S:	Oh okay (*reaches over the computer to grab Prince's dry-erase board*)

19	S:	I know what we need to do. We just need to make... if we find...
20	P:	Hey what's our um...
21	S:	Look, look! Look! Look!
22	P:	No, sir!
23	S:	No! Look what we need / to do, look!
24	P:	/No, nonononono, no, no! (*makes slashing motion with his hand)*
25	S:	Make zero-zero
26	P:	No, we- yeah, we have to find the zero-zero, cause then I'mma just turn the rest of it blue. What color blue is this?

In turn 19, Sam attempted to shift Prince's attention away from his own solution and towards Sam's new idea, again making a bid to position Prince's ideas as uninteresting. However, once again Prince forcefully rejected this positioning, with a strong "No sir," and a repeated "no no no no."

Phase 2: Positioning uncontested

The initial interactions between Sam and Prince suggest that Prince had a credibility deficit with respect to Sam, seen in Sam's repeated positioning of Prince's ideas as obvious and unworthy of attention. However, Prince consistently rejected this positioning. Still, as the episode went on, others entered the interactional space and contributed to Prince's positioning as having a credibility deficit. For example, about seven minutes into the interaction, Prince asked for assistance from Victor, the class TA. Prince was trying to determine the coordinates of the NetLogo canvas, with the goal of typing a command for the y-coordinates. However, the TA failed to listen, and in so doing positioned Prince as confused, once again creating a credibility deficit.

1	P:	How do we put, um, the graph on it?
2	Victor (V):	Do what?
3	P:	Put a graph.
4	V:	Hit setup. Go to code… your code. There's a problem in your code. It's fussing at you for something.
5	P:	Oh I didn't, I didn't finish, like I was looking for-
6	V:	(*Cutting off Prince*) Oh well then it won't do anything.
7	P:	I know, I was looking for the um/ the grid
8	S:	/ We need to do this! We need to write, we need to write, dude. We need to write…
9	V:	Oh, oh, the grid. You can't turn the grid on. (*Prince looking at the screen and nodding)*
10	S:	(*Starts repeatedly poking Prince on the shoulder)*
11	V:	But you can look at the code and figure it out.
12	S:	We need to write the coordinates. (*Prince nods slightly at Sam, still attending to Victor)*
13	V:	Alright, hold on (*Takes control of laptop, clicks back to code*)
14	P:	(*Following along with Victor, eyes on the laptop screen*)

By interrupting and not listening to Prince's strategy or what he is trying to accomplish, Victor appeared to approach the question from Prince with an assumption that he was confused, seen in particular in turn 4. This positions Prince again as having a credibility deficit. In turn 7 Prince gently rejected Victor's bid, stating that he knew his code was unfinished and that unfinished code wouldn't run, but he was focused on something else for the moment. At no point in the interaction was Prince asked what he was doing or trying to do, but instead Victor immediately assumed that Prince was confused and in need of explanation.

Prince ultimately completed and tested his proposed solution, which would have fixed the bug. However, he made a minor coding error. Instead of telling Netlogo to color blue all pixels with y-coordinates *greater* than five, he wrote to color in all y-coordinates *less* than five, resulting in the bottom two-thirds of the screen being colored blue, and a small white strip at the top of the screen. Seeing this failure, Prince looked at Sam and said "I tried," and while Sam looked back at him, adds "hey buddy, you failed too." Sam sat back up, grabbed the laptop and pulled it towards himself, saying "alright, watch me. Watch me." Prince asked "what are you gonna do," but Sam didn't respond and instead began typing.

As an additional example of continued positioning, Ms. Turner, the lead teacher, came to check on the boys' progress around 15 minutes into the episode. In this moment Prince made one last bid to share his idea, and Ms. Turner seemed interested, and even impressed. However, her own apparent lack of faith in Prince's ideas, along with repeated interruptions from Sam, served to re-route Ms. Turner from Prince's code, and Prince sat back to watch as the teacher and Sam began to physically talk and work over Prince.

2	Ms. Turner (T):	Where are you guys? Still on Paint a Square?
3	P:	mmmhmm. I made, um, (*unintelligible. Clicks "interface" and motions toward white rectangle in the top middle on screen*).
4	T:	Oh you did that! Okay.
5	P:	I know, like, so it's "ask patches". (*S clicking "make square" button repeatedly*) Duh, duh (*motions with his hand in an "L" shape*)
6	S:	We messed up "setup" didn't we.
7	P:	It's pycor. It's gonna be pycor less, less than, less than 5.
8	T:	Okay. Try that! Try that. He's got pxcor greater than -5. You want. Are you adding it here are you making another line?
9	P:	(*looks at teacher and opens mouth as if to answer*)
10	S:	I know what I did was wrong. But we should do this. Ask patch O 3. Well, whatever one it is O O. Ask neighbors, but also have it turn white too. That would make a square.
11	T:	Let's see it! (*directed at S. P nods)*
12	S:	I don't know how to make the one in the middle white too. Oh! After I do it, make O O white. Okay so that's how it's supposed to work. I think. (*looks to teacher. Turns computer to face himself more.*)
13	P:	(*Watching the screen, listening to Sam*)

In this interaction, Prince's idea was once again positioned as less interesting, and even as not belonging to him. In turn 4 Ms. Turner responds to Prince's code with a retort that appears surprised, saying "Oh you did that! Okay." This surprise suggests that she did not anticipate that Prince might have written advanced code, further positioning him as having a credibility deficit. Prince does not appear to notice her surprise and continues to explain his idea. However, in turn 8, the teacher stated, "He's got pxcor greater than negative five," attributing Prince's code to Sam. Before Prince could respond, Sam interrupted, pulling the teacher's attention away. This shift in attention away from Prince's idea was completely uncontested, a contrast with Prince's earlier responses, where being positioned as having less worthwhile ideas was something that he actively rejected.

Phase 3: Positioning accepted

As a final example, towards the end of the episode, Sam, gets frustrated with his code, not completely understanding what to do. He pushes the laptop back to Prince for the first time in around 30 minutes. After Prince explains an alternate approach, Sam asserts that he can do it faster.

1	S:	Is it make another square somewhere else? Or is it move that square?
2	P:	You wanna just… make another square? It didn't say it has to be a big square, it just has- it says make another square.
3	S:	Shut up!
4	P:	It just says make another square, so you can put, um… do the same code
5	S:	Let me show you
6	P:	No, do this code with a different, um, number.
7	S:	This number?
8	P:	Different number. Do that code, nonono, yeah yeah, but just put it with a different number
9	P:	But do the same thing you just did right there, but with a different number
10	S:	Nine, nine
11	P:	No no no, keep that, keep that right there, go right here and then change… copy and paste
12	S:	I hate when you're trying to tell me... you do it!
13	P:	Okay (*S: Growls*)
14	P:	So, copy…
15	S:	We jus- are we just gonna make another tiny square somewhere else?
16	P:	We're gonna do that and then we're gonna ask neighbors
17	S:	okay, so basically just make another tiny patch somewhere else?
18	P:	Yeah
19	S:	I could do it faster
20	P:	I know, I told you to do it
21	S:	Why? ... Nine-nine...

Despite the fact that turns 2-11 involved Prince proposing a solution that he was attempting to explain to Sam, Prince again was positioned as a less capable coder. Sam's frustration, which led him to turn the computer over to Prince, was immediately followed with his continued efforts to understand the proposed solutions. Once that had been accomplished, Sam made an immediate bid for his own greater competence, saying in turn 19 "I could do it faster." In previous interactions with Sam, Prince was more likely to defend himself from a positioning of being a less capable coder. In this moment, however, he conceded to Sam and affirmed him as the faster coder by saying "I know" in response on line 20.

Overall, Prince spent a total of 5 minutes on the laptop. Upon relinquishing it to Sam, Sam controlled the laptop and the thinking for the next 30 minutes, and the teacher will eventually write a solution for them. The group never returned to Prince's original idea, which would have resulted in the desired white square had an inequality symbol not been mixed up. This was a collective loss of knowledge not only for Sam and Prince, but for the rest of the class, as Prince had a unique solution.

Broader storylines: Resources tacitly accessed in interaction

The *Code Your Art* camp, in general, was a collaborative and creative environment where students were frequently sharing ideas and creating new things. However, the debugging activities were different in that there was a pre-defined goal for all students. Previous research on pair programming suggests that a focus on speed can create inequitable outcomes between group members (Lewis & Shah, 2015), and this activity's structure invited a familiar classroom storyline of competing to be the student who is first to get the right answer. There were many times when both boys, especially Sam, appeared to be working *against* each other, insofar as they compared their relative success and emphasized failing as something to be embarrassed about. This supported a competitive dynamic that became a resource for positioning; if we are competing, someone must by definition be better than someone else. This also connects with a broader narrative that failure in STEM is indicative of broader incompetence. This could possibly account for why Prince was quick to give up, as it is better to be caught not trying than to be caught making a mistake.

A key element of epistemic injustice is identity. Though there was never explicit mention of race in this episode, there were moments when it seemed that Prince's race was made visible. For example, when Prince first took control of the laptop, Sam reached out and squeezed Prince's hair. The hair touch draws upon a broader storyline of the exotification of Black people and Black features, such as Black hair. It appeared that Prince was further racialized by the teacher, during a period in which Prince put his head down. His teacher encouraged him to "make a rap about it," assuming that rap was the way to engage a Black student in coding, even though Prince had expressed a very high engagement with the debugging activity before being consistently undermined. These interactions suggest to us that race, and specifically, the idea that "Black students aren't good at STEM," was recruited as a storyline in these interactions. This storyline created tacit expectations of Prince, and then was used to make sense of Prince's behavior, specifically if he had a question or was simply quiet.

Discussion, conclusion, and implications

In this paper we used positioning theory to understand how and why Prince's participation appeared to change over time, ultimately resulting in what, to us, seems a clear case of testimonial injustice. The first-order positioning of Prince from the teacher, teaching assistant, and Sam all seem to assume that his ideas are unworthy of serious attention. These moments of established credibility deficit were initially challenged by Prince, but it took few repetitions for him to become increasingly silent and accepting of the position that was given to him. Though Prince's self-removal from the activity can be seen as an act of self-preservation, it also highlights his own apparent acceptance, or at least agreement, that his ideas are less valuable. Finally, these episodes of epistemic injustice resulted in real intellectual harm. Prince's idea to paint the top and the bottom of the strip blue, leaving a white square in the middle was an important contribution that, uniquely among other solutions, coordinated mathematics with programming. The idea would have worked, had it not been for a small coding error. However, the result was taken as a confirmation from both Sam and Prince that Prince's idea was not worthwhile. This ended the opportunity to investigate Prince's idea fully and resulted in a literal loss of knowledge about coding. We relate these moments of positioning of Prince in relation to his ability as a computer programmer to his racial identity through what seemed to be racially motivated comments. In this way, the broader storylines that were drawn on as resources in the interactions helped make the repeated assumption that the Black student in the pair was less likely to have a good idea, an assumption that was seemingly leveraged by everyone in the interaction.

Although we argue that Prince's race played a crucial role in his positioning, we also note that, consistent with the findings of Lewis & Shah (2015), the storyline of "competition" also offered an important resource that contributed to this interaction. This could have been mediated by explicit instruction about how students should work together, which did not happen before students began this activity. We know that creating group work without defined roles for each person, or without teaching groups how to work together is often ineffective (Cohen, 1994), and in fact, this lack of structure enabled all participants to recruit and use storylines that ultimately did harm. Still, we see this episode as representative of greater systemic trends in which Black students and their disciplinary contributions are regularly sidelined and ignored due to assumed creditability deficit based on their racial identity. The persistence of episodes like the one outlined here perpetuates the acceptance of Black learners' positioning as less capable and ultimately contributes to Black students' disengagement in disciplinary practices and in STEM fields more generally.

Aesthetics of Authenticity for Teachers' Data Set Preferences

Victor R. Lee, Stanford University, vrlee@stanford.edu
Victoria Delaney, Stanford University, vldocherty@stanford.edu

Abstract: This paper explores secondary school teachers' aesthetic judgments of data sets for prospective use to teach data science. Twelve teachers were interviewed and asked to examine and select from side-by-side data sets the one that would provide a more authentic experience for students. Situating our work in the "Knowledge in Pieces" epistemology, we drew upon diSessa's (1993) notion of an aesthetic – a knowledge system for appraisal and judgment. We examined what sensitivities were expressed and how judgments were made and supported. We observed that teachers drew upon at least three senses of authenticity to characterize and select data sets: authentic as messy, authentic as requiring more work, and authentic as involving computation. Identification of these ways of determining authenticity represents an initial step in better understanding how teachers appraise data that could be used in their teaching.

Introduction

In their review of how data are being used as part of investigations and inquiry experiences in middle and secondary classrooms, Lee & Wilkerson (2018) examined the current state of learning sciences research related to the use of curated and public data sets in classrooms. Specifically, they found substantially less guidance for how educators can best use these kinds of data, and they stressed that this was an area where more research and support was needed. As researchers in this space who expect that the design of rich data experiences will become a more persistent concern for the learning sciences, we are trying to address these gaps. We are imagining a future where teachers are able to obtain and introduce quantitative data sets into their classrooms much in the same way that a teacher might select and include what they consider to be a related or useful news article or website that they have discovered online as an instructional resource. In that scenario, some sets of data will be selected and be judged to be more or less useful in their teaching. We ask in this paper how those judgments get made.

Beyond being a relatively understudied area in the emerging space of pre-collegiate "data science education", we subscribe to a model of classroom instruction that involves teachers designing their own or adapting existing curricula (Brown & Edelson, 2003). This makes teacher selection of data sets one of the many design decisions that get made. However, in thinking about this design decision, it is unclear the process that teachers will go through in their decision making. We also have little existing research on which to base teacher learning experiences that will help teachers to be even more thoughtful and reflective of their data selection decisions. Rather, research on teachers and their thinking related to data sets focuses largely on their conceptual understandings (often presented as misunderstandings) of certain core topics involved in data analysis (Batanero, Burrill, & Reading, 2011).

As there are now growing calls to develop an area of data science education (Lee & Wilkerson, 2018) and for learning scientists to contribute to research and design supportive of it (Wilkerson & Polman, 2020), we believe some new work on teacher thinking about data sets is needed. To motivate this in terms that are more practice-oriented, we might imagine a situation where a high school teacher wants to bring in a real data set from professional research that relates to natural disasters. If they live in an area that is known to have major fault lines and seismic activity, then seismology data might be more desirable. However, if the teacher is working in an area where hurricanes and flooding are the major concern, then data on hurricanes might be more desirable. Decision making could be as simple as deciding what is more locally relatable, but there could still be a number of potential complicating factors. The quality or amount of data may differ, or the structuring of the data – such as using numbers on a logarithmic scale - may introduce challenges that lead teachers to be more reluctant to use them. Furthermore, a geography teacher may have different priorities than an Earth Science teacher, and they may have different priorities still from a mathematics teacher.

Regardless of whether teachers are doing the work of selecting data sets or whether curriculum or software designers have pre-selected data for them, some consideration of how teachers judge and appreciate data is needed. In this paper, we report on some initial efforts to examine that. Our focus is on data that is thought to be supportive of an authentic learning experience related to data science. The theoretical perspective we draw from is based in the "knowledge in pieces" epistemology (diSessa, 1988). In the section below, we discuss theoretical bases involving aesthetics and authenticity. Following that, we present some initial results in our efforts to understand teachers' aesthetics for authenticity.

Theoretical perspectives

Knowledge and aesthetics

This work is situated within what learning scientists refer to as the "Knowledge in Pieces" (KiP) epistemology (diSessa, 1988), which is most prominent in conceptual change research. It has also been recently used to model knowledge in interaction (diSessa, Levin, & Brown, 2016). As a theoretical perspective, KiP provides an alternative to descriptions of student knowledge that are critiqued for using imprecise, or arguably inaccurate, terminology (diSessa, Gillespie, & Esterly, 2004). A common use of KiP has been to challenge cognitive models of knowledge that make strong claims about context invariance. For instance, the claim that students come to instruction with rigid misconceptions that must be disproven is one that has come under critique from the KiP perspective. The proposed alternative to a misconceptions view is to think of student knowledge as involving more atomistic pieces of knowledge that are cued in response to contextual information (Smith, diSessa, & Roschelle, 1993). One interaction in which this has been made more apparent is in Piagetian-style clinical interviews. In such interviews, occasions where students seemingly contradict themselves or change their minds within minutes of having already given a seemingly confident and definitive explanation for a phenomenon are often cited as a demonstration of how a KiP perspective can be especially useful (Sherin, Krakowski, & Lee, 2012).

Some of the most prominent KiP work emphasizes the specification of certain kinds of cognitive resources that play key roles in dynamic reasoning processes (e.g., Hammer et al., 2005). Another related area of work within the KiP tradition is the identification and description of what diSessa calls *aesthetics* (diSessa, 1993). Aesthetics are "rich but structurally limited knowledge systems, which, notwithstanding their richness, appear fluid, data driven, and involve situation-specific reasoning…and idiosyncratic justification." (p. 187). As diSessa describes them, aesthetics provide judgments of similarity and preference. They also serve to provide hunches and intuitions with varying levels of confidence. Aesthetics are involved in a range of situations. One of the most well-known is the sense of mechanism that is invoked in commonsense physics reasoning. For instance, the sense of mechanism for physics helps students to predict behaviors of objects in motion or determine where forces are involved in a physical situation (diSessa & Sherin, 1998). Another aesthetic is the knowledge system that develops in order to recognize the law of large numbers within different probabilistic situations (Wagner, 2006). While these are mathematics and science-oriented examples, diSessa (1993) is explicit about stating that aesthetics are applicable to a range of domains. Knowledge about interpersonal relations is suspected to part of a social aesthetic. Indeed, this suspicion is explored and applied to a case of a teacher's ideological reasoning by Philip (2011). In that example, the aesthetic system serves to make judgments about students and explain why some students succeed or fail at being students.

One goal of the current paper is to provide some initial description of aesthetics involved in evaluating data sets. In particular, the aesthetics that are being considered are those of high school mathematics and statistics teachers. We selected these teachers because they were likely candidates for teaching data science as a standalone topic or course. While we focus on mathematics and statistics teachers, we do note that where and how data science should or eventually will be integrated into the curriculum is unsettled. Informally speaking, based on research workshops and summits, interest has been expressed from those in the computer science education, math & statistics education, and science education communities. Regardless, there are cases of standalone data science courses being deployed in large school systems (see Lee & Delaney, 2021) and being deemed eligible because they count as fulfilling the same requirements as that of a high school statistics course.

Authenticity

Learning sciences has often stressed authenticity as a valued priority in the design of learning experiences. Accessible, but authentic forms of scientific inquiry, are often pursued (Edelson & Reiser, 2006). This may involve supporting students in scientific modeling (Schwarz et al., 2009) or providing students access to scaffolded versions of professional tools like GIS systems (Edelson, 2004). In this treatment of authenticity, similarity or congruence with respect to professional practice are prioritized.

At the same time, research in the learning sciences has also treated community-based forms of knowing, understanding, and acting in the world as authentic, although those instantiations may not bear immediate resemblance to professional disciplinary practice. A well-known example comes from Lave and colleagues who documented how learning how to do solve mathematics problems to determine the best buy of a product in a traditional classroom can look quite different from what actually happens when one is determining best buy of a product while shopping in a real-world setting (Lave, Murtaugh, & de la Rocha, 1984).

That we can apply authenticity to these different situations suggests that there may be different frames of reference for what makes something authentic. Indeed, there is evidence for this in some of the psychology literature. In his summary of prior research on authenticity, Newman (2019) identified multiple ways by which we judge authenticity, at least with respect to objects. These include historical, categorical, and values authenticity. Historical authenticity implies a connection to a particular person, time, or place. An authentic Picasso painting would be one that was actually painted by Pablo Picasso. Categorical authenticity would match existing beliefs and requirements for a category to which the object belongs. Authentic Neopolitan pizza could be purchased and enjoyed outside of Naples provided that it was made with the correct ingredients and followed a specific preparation process. Values authenticity would involve consistency between internal state and external expression. While two politicians would say that they support racial justice, one might come under fire for being inauthentic whereas another might be seen as actually authentic.

It is unlikely that these treatments of authenticity are exhaustive, especially considering these were presented primarily with respect to objects. However, this illustrates that authenticity can be complex and subject to various evaluative criteria. In light of that, the question we examined was what data sets would our participating high school teachers deem as providing a more authentic experience for students. Our goal was to get some traction on understanding an authenticity aesthetic, as it relates to teaching high school data science.

Methods

Research participants

The participants in this study were 12 secondary school math and statistics teachers. These teachers were not recruited through a randomized process. Rather, they were solicited from existing contacts in schools and through snowball sampling. There were 6 men and 6 women who participated. These individuals had a range of 2 to 31 years of teaching experience, with the average being 13 years. These teachers came from a mix of public, private, and charter schools in the US, and some taught other courses, such as computer science, as well.

Procedure

The teachers participated in a videorecorded interview that lasted approximately one hour. These interviews were completed during the COVID-19 pandemic and thus were done via video communications (i.e., Zoom). The bulk of the interview involved the teachers being presented with two pairs of data sets as tables in CODAP, a free web-based educational tool for examining and visualizing data. During the interview, the teachers were provided a brief introduction to CODAP and shown what were its visualization capabilities using a data set that was provided in the software. Because these were done via Zoom, the interviewer explained that she would show the teachers the data sets as tables and at any time they could request that the view of the interviewer's shared screen be changed (e.g., scrolling) or that a data visualization be made. Surprisingly, very few teachers asked for visualizations to be made.

One pair of presented data sets were of passengers on the Titanic. Titanic data were selected as they are common in online and undergraduate data science courses and high school statistics courses. One Titanic data set ("Titanic A") came from the data website, Kaggle.com, which is used by data science enthusiasts, holds data sets on a wide range of topics, and hosts competitions for users. The other Titanic data set ("Titanic B") came from the *Introduction to Data Science* curriculum (Gould et al., 2018) used in a number of high schools in the United States. Titanic A had 891 cases, whereas Titanic B had 1000 cases.

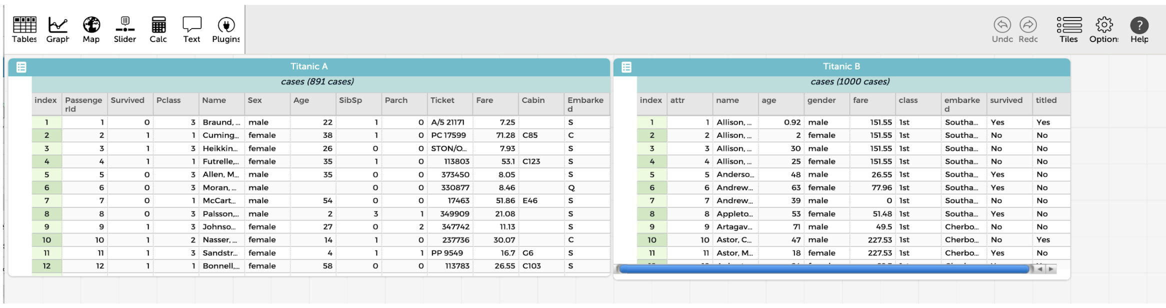

Figure 1. The Titanic A and Titanic B data sets.

The other pair were of popular movies and their box office revenue. One came from the *Bootstrap:Data Science* curriculum ("Movies A"). *Bootstrap:Data Science* is one of multiple *Bootstrap* curricular units that were developed to integrate computer science into curricula. The other movies data set ("Movies B") came from the above mentioned *IDS* curriculum. Movies B was much larger than Movies A in that it had 4935 cases while

Movies A had 100. These data sets were downloaded unaltered from their source curricula resource sites. While there was over an order of magnitude difference in the sizes of the two data sets, we chose to use them as they were because that was how they were made available in their respective curricula.

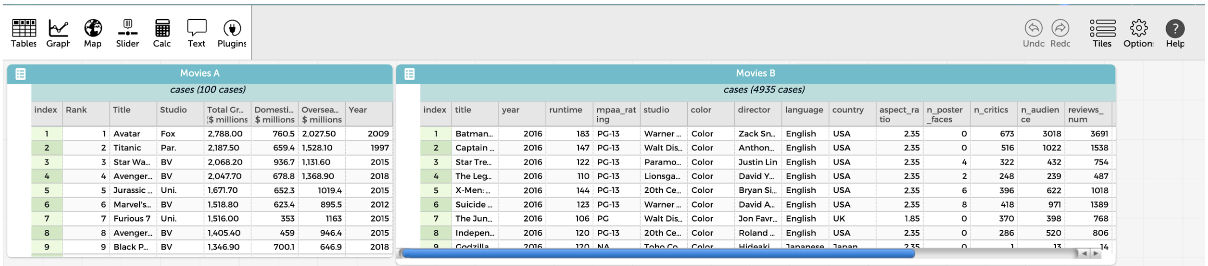

Figure 2. The Movies A and Movies B data sets.

We would also like to note that *B:DS* and *IDS* were selected because their development was funded by the United States' National Science Foundation, and they are among the only complete secondary data science curricula freely available online. In a separate paper (Lee & Delaney, 2021), we have reported on some content analyses of these two curricula and noted some differences between the two. Among those differences were in how large and how varied the data sets were used throughout each curriculum. Those differences motivated us to inquire about how teachers would judge these different data sets. At the same time, the data sets were different topically across the two units. Movies was one common topic, and Titanic was selected for the reasons stated above.

During the interview, the teachers were asked which data set will give students the most authentic experience of working with data in the context of a course they created that addressed data science. Those segments of the interview were our focus for this paper.

Analysis

The most common form of analysis for KiP oriented work is *knowledge analysis* (diSessa, Sherin, & Levin, 2016). Knowledge analysis typically involves video or audio capture of knowledge in use. For instance, interviews that involve participant sense-making about everyday activities in 'scientific' terms is one common interaction genre. Other approaches can involve paired problem-solving or work with a microworld.

Regardless of what type of interaction is recorded, those records are transcribed and then episodes are selected for iterative review and theory building. This may involve systematic and comprehensive coding, although when that is done, the goal of coding is to support theory building rather than emphasize frequency. Theory generation as part of knowledge analysis adheres to several core principles including a commitment to describing knowledge in terms of mental representations and fine grained and nuanced detail of those representations in action that is tightly connected to the presented data.

Reports of knowledge analysis tend to involve episodes of reasoning on the time scale of seconds to minutes with detailed description of knowledge elements at work. The reports are evaluated with respect to the adherence of theoretical claims about knowledge to the provided transcript excerpts and the potential for extending those claims to situations beyond those that are presented. Knowledge analysis reporting generally asks the reader to decide, assuming a KiP perspective, whether they are convinced of theoretical assertions that were motivated by the data.

For the current study, the interviews were transcribed and subject to multiple coding passes and joint interpretation sessions involving the authors. The coding passes varied from labeling content of what was discussed to what was being referenced within a data set to the sense of authenticity that was being evoked by the teacher. Some categorization of preferences was also done. Ten out of the twelve teachers picked Titanic A over Titanic B as providing a more authentic experience. For the Movies data sets, 11 picked Movies B.

Results

Authenticity as messy

Part of the aesthetic appeal for some of the teachers appeared to be based on the sense of authenticity as the data being 'messy'. To illustrate, we provide an excerpt from an interview with Kiera. The interviewer was trying to get clarification from Kiera as to why she had just picked Titanic A over Titanic B. Kiera began by talking about Titanic B.

Kiera: I was saying that B has exactly 1000 cases, which is just such a nice number, you could make percents out of that easier, but is that just a coincidence, or is that manipulated data, whereas A seems a little bit more raw, I guess. B seems a little more cleaned up. So I guess if we're talking about the word authentic, I guess A.

While Kiera had many points to make, the one that is most relevant currently is in the second half of her utterance. She described Titanic A as "a little bit more raw". In contrast, Titanic B could be "manipulated data". If it was not manipulated, then for it to have 1000 cases would have to be a "coincidence" rather than to be expected. Moreover, the number 1000 had the quality of being "nice". Given just this statement, it would be hard to ascertain with confidence. It could be that it has something to do with 1000 being a decade number (i.e., multiple of 10), which has familiarity in the number of fingers we have on two hands (Domahs et al., 2015), our monetary system, and in how we often count and compute numbers in many languages (Murata, 2004). Visually, it also has repetition of three zeroes, making it feel less random as too much repetition is seen as less likely in chance events (Nickerson, 2002). Regardless, the aesthetic system extracts the number of cases and infers that it is special and less probable, making Titanic A more authentic. This observation appeared for multiple teachers in our study.

Authenticity as messy also appeared in other forms. Don, quoted below, was sensitive to the presence of organization in Titanic B but not in Titanic A.

Don: Yeah, so, I think that-they [students] would find it challenging that it's-well B is now organized alphabetically…If I wanted to be authentic, I think that I would probably choose A, because the data-is not organized, it's a little bit less clear on what's happening there, some of-like, the cabin is only listed for some of the people-Like, that's the same way, in the real world, you can't just get the 300 million people in the United States and-and you chose 1,000, you won't reach the thousand.

In this initial part of this selection, Don was conveying that his appraisal was that Titanic A was "not organized", or as we characterize it, disordered. Part of this disorganization came as a contrast from alphabetical order he recognized in Titanic B from looking at the *Name* column. From there, he continued with other ways he sees disorder – namely, the presence of empty cells appearing in the *Cabin* column ("the cabin is only listed for some of the people"). This suggests that for Don, detecting incompleteness is part of authenticity. To support that, Don made an analogy to "the real world" where if one were tasked with contacting 1000 people in the United States as part of a data collection effort, the thousand could not be reached. Authentic data experiences should involve encounters with incomplete data. Contacting 1000 people and succeeding in reaching them had a feeling of being orderly, whereas not getting all information was more disordered and to be expected.

Authenticity as requiring more work

While we saw Don state that parts of Titanic A were "a bit less clear" to refer to disorder or messiness, this appeared to also be connected to an aesthetic judgment related needing to do more work with the data in order to make inferences from it. There are indications of some underlying resistance or additional work. This was elaborated in the same utterance, of which another excerpt is provided below.

Don: So I feel like A is more challenging to look at, for, it's labeled a little bit less clearly, organized a little less, a little more abstract, *survived* is numbers and the *Pclass*-but, I think that then the flip side to that, I guess, is that B is a little bit easier for kids to deal with. And then, they could still-A requires the challenge of figuring out what the heck is going on, and then doing the data analysis. Whereas B is slightly, but not perfectly, organized, in a way that the kids would be able to attack the learning objectives of the class a little bit easier. But A is closer to what real life data would actually look like.

In some way, Titanic A required that students work more and work harder. Evidence for this appeared with his comparative statement that "B is a little easier for kids to deal with" and "A requires the challenge of figuring out what the heck is going on". Part of the work to be done comes from understanding the header labels, as they had, such as *PClass*. (At a separate time, Don stated "*Pclass*, I'm guessing...three is the more expensive one, or, one is the more expensive one, I don't really know yet. I guess I could look at the *fare* and maybe figure it out."). Figuring out what *PClass* referred to and how the numbering system for it worked required additional steps to complete.

Authenticity as more work also appeared when Don was asked to select the Movies data set that would provide students with a more authentic experience.

Don: I would choose [Movies] B, because, it has data that is not necessarily necessary, which I think is-that's how you're going to get data, otherwise they're doing the work for you. Like if you ask your school principal, like hey, can I get some demographic data on the students at our school and the grades that they have? They're not going to just give you two columns, like race, GPA, maybe that's what you wanted to know, but they're not going to do that for you,

As Don described it, there is additional work to do with Movies B to discern what information (i.e., variables) is desirable in the first place. This is the result of having more columns than what is necessary. This implies some searching, selecting, or reducing must be done. Don illustrates this through an imagined scenario of asking the school principal for data. In this imagined scenario, he might want information related to two variables, race and GPA. Assuming the school principal were willing to share the data, "they're not going to just give you two columns". The school is "not going to do that [data reduction] work for you". That there is work that the school will not do implies that there is additional work.

A similar sentiment that authentic means additional work appeared in Roscoe's selection of Movies B as providing a more authentic experience.

Roscoe: I would choose B, mainly for the volume of data in it, the number of cases, and the fact that it has quite a few attributes, and you have to puzzle down which ones are the ones who want to look at. Also, it looks like there's... I see a couple of NAs in there, I don't see any of the others, I suspect there may be more missing data problems or... outliers or things that have weird attributes on them that you have to deal with, which is always a real problem with real data sets.

There were a few appraised qualities of the data that he noted that suggested more work. One was that there was abundance in the data (which we believe is likely its own aesthetic judgment that we do not detail here. In that aesthetic judgment, large sets are more authentic. Consistent with a KiP model, other knowledge can be cued. In Kiera's example above, 1000 cases in the Titanic B data was suspicious, meaning that a preference for B was superseded by the authenticity as messiness judgment). Abundance appeared in "the number of cases, and the fact that it has quite a few attributes [columns]". Here, the mention of attributes is of current interest. Because there were many attributes, students would have to do the work to "puzzle down".

Another quality of the data was the presence of NAs. These were values that acted comparable to the empty cells that Don noted above in Titanic A data, as this was described by Roscoe as a part of "missing data problems". These were grouped also with "outliers or things that have weird attributes on them that you have to deal with". In having to deal with them, there is added work, whether it is having to make additional decisions (such as whether to exclude those) or caveats (such as the outlier having an influence or inferences being based on less than the total number of cases).

Authenticity as involving computing

One other authenticity judgment we discuss came in the form of connection to computing. Data science was something virtually every teacher saw as involving computers and some amount of programming skill. For authentic experiences, some connection to computing seemed connected to a sense of authenticity. For example, Joan immediately noticed the presence of values of "0" and "1" and identified Titanic A as more authentic. She explicitly stated the following:

Joan: I guess as I teach computer science [in addition to other courses], I like the zeros and ones because it lets me have a conversation about bits and binary [in A].

The main connection Joan made was that it involved an encoding system (binary) that was connected to how computers store information. The presence of "1" and "0" values was mentioned by several teachers for Titanic A in the Survived column. Separate from being an encoding that was associated with computers, the binary values were also seen as being more easily used for computing values. Drake illustrated with the following rationale for choosing Titanic A.

Drake: I mean I think Titanic A would give them a more authentic experience. If I have to say why, it's that it's quantitative, and I think it's easier to work with quantitative values like, giving the values survived a value or 1 or 0 is much easier to work with than if it says yes or no, like they could much more easily figure out, okay well how many people survived? Well just add up.

Drake was drawn towards the values being quantitative, although there were quantitative values in all of the data sets. The quantitative values he focused on, however, were “1” and “0”. That encoding for survival would involve a simple matter of adding all values together. There would not be a need to transform written words into numbers that could be manipulated through calculation.

Another way that computing was implicated was in how computers would be necessary to do the work. Roscoe noticed features of the data related to the production of models for real-world phenomena. He elaborated on his noticing of data abundance in his choice of Movies B:

Roscoe: And like I say, Movies A is sort of light on the number of cases. Now, if I was just doing maybe a statistics class, and we weren't actually doing... I could imagine in statistics class, you might not do as much programming. And you know, you're not using it to try to train some model. It may be more appropriate to have fewer things there, that are less confusing and having less data available so that you can actually scan through it and see what the issues are, with, I guess 5,000, there's a chance, you can still stomach going through it, sort of scrolling through everything to see what's there. But definitely 100, people are going to go and look at the entire dataset.

The abundance of data, according to Ramsey, necessitates the use of computational tools and procedures central to data science. This was different from what he considered to be a statistics class where “you might not do as much programming” and the data are not being used “to train some model”. With the larger number of cases in Movies B, which also likely cued the “authenticity as more work” judgment, he suggested it was less likely that students would try to go through thousands of values. He expected that with just 100 data points (Movies A), students would just look at the entire data set to get the information they wanted rather than use computing tools.

Discussion

Thus far, we have examined high school math and statistics teachers’ aesthetic for data sets that support authenticity with data science work. These include sensing authenticity when the data was messy, when using the data required extra work, and when computing had some connection to the work that would be done with the data. These judgments are not exclusive. We suspect from our reviews of the transcripts that they may reinforce one another.

Looking at teachers’ sense of authenticity is consequential for a future where learning scientists will be participating in the work of designing data science educational experiences and for helping educators make judgments on how to provide students with high quality learning opportunities. Our current assumption as learning scientists is that authenticity is desirable. This paper is an initial effort to characterize what that could mean. Having made some observations about how teachers see authenticity in data sets for high school data science instruction, there must also be consideration of the extent to which authenticity is desirable by teachers. It may be that the authentic data sets involve work that the teachers appreciate but struggle to include given the constraints of existing school structures. For instance, data cleaning is a common data science activity and one that takes a substantial amount of data scientists’ time. However, just because it takes much of their time, it may not be something that educators feel is worth proportional instructional time. Indeed, we have begun to examine this in our data. At a later point, we asked teachers to select data sets based on what they thought would be best pedagogically. Of the ten teachers who selected Titanic A as more authentic, five of them said Titanic B would be a better choice pedagogically. However, for the Movies data, the same data set selected for authenticity was also selected by teachers for pedagogical considerations. Examining pedagogical aesthetics and how they complement or conflict with other aesthetics, such as authenticity, remains as work for us to do in the future.

“That Was Mindblowing”: How Reading with a Social Robot Enhances Science Learning Experiences

Joseph E Michaelis, University of Illinois at Chicago, jmich@uic.edu
Bilge Mutlu, University of Wisconsin-Madison, bilge@cs.wisc.edu

Abstract: Learning sciences research has demonstrated the importance of social interactions during learning to help promote deep and meaningful understanding through a process of co-constructing knowledge, but homework reading is typically done as an isolated exercise. We have developed a social robot to provide social interactions during reading activities with middle- school children, and in this study report on how interacting with the robot affected the learning experience. Our thematic analysis describes direct and indirect benefits from reading with the robot. We conclude with theoretical and practical implications of these results.

Introduction

Educational researchers and practitioners have increasingly called for a greater focus on students developing deep and interconnected understanding of content, rather than the memorization of facts and procedures. Learning sciences research has demonstrated the importance of social interactions during learning to promote this deeper learning through a process of co-constructing knowledge (Miyake & Kirschner, 2014). Yet, most homework assignments that ask students to read textbooks or other materials, used frequently in US education and in science curriculum, are typically done in isolation. Some approaches to supporting student learning at home include educational technologies that offer aids for comprehension and problem solving, but these too often focus on procedural learning and rarely include a social component. Computer supported collaborative learning (CSCL) technologies can effectively support social interactions during learning, but require coordination between learners when used at-home, that can be difficult for elementary or middle-school aged students. To benefit from social interactions while learning in homework reading scenarios, we need educational technologies capable of sharing the reading experience and providing critical social interactions during these learning opportunities when human-human social interaction is unavailable or limited. Our goal is to address this need by creating augmented science reading activities with a social robot that can provide knowledge supports through social interactions to promote deeper understanding of science content.

Theoretical framework

Our work is guided by a socially situated or sociocultural learning perspective (Vygotsky, 1978). Research on socially situated learning demonstrates how social interactions transform activities into collaborative experiences where knowledge is co-constructed with others. Social interactions encourage students to take an active role in their learning and engage in meaningful dialogue about content. These interactions also provide opportunities for scaffolded knowledge supports that simplify or make connections within and outside of the content (Hurst et al., 2013). While working together, learners build on and explore ideas with each other that helps to connect new concepts to other knowledge, and to summarize and synthesize what they are learning (Miyake & Kirschner, 2014). In this way, learners build rich and meaningful understanding, where they have grappled with concepts

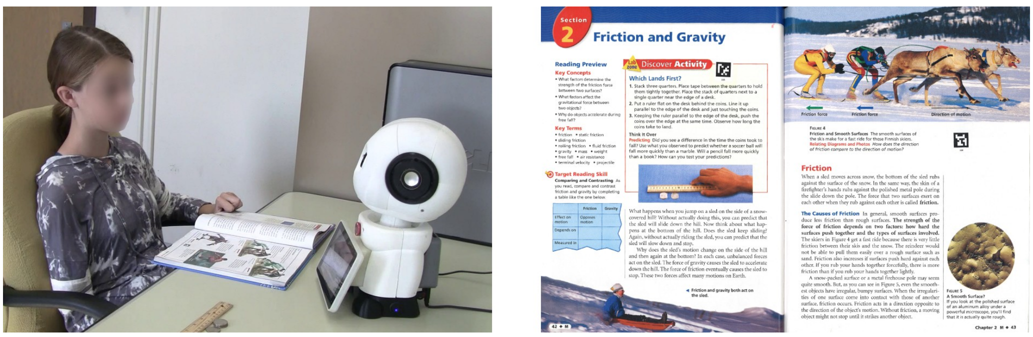

Figure 1. Child reading with Minnie (left). Textbook page with discover activity and AprilTags (right).

rather than simply tried to remember them. This social approach is underexplored in reading for learning, but some methods such as paired reading, have proven effective. Topping et al. (2011) demonstrate that paired reading, where students read out loud together on a regular basis, has long-term positive effects on reading ability that were highest for *near-peer* tutoring, where partners are close in age, and when reading pairs stopped to talk about the book every 5-7 minutes. These types of collaborative reading activities have also been found to promote greater reading comprehension in science and social studies content (Boardman et al., 2015), and can be seen as a template for creating socially situated reading experiences to improve learning.

The computer supported collaborative learning (CSCL) research community is a leader in designing technologies to support social interaction during learning (Kreijns et al., 2013). In these scenarios, the technologies, often web-based applications, are typically designed to facilitate collaboration between two or more learners, and are effective by supporting students in posing questions, exploring lines of inquiry together, practicing reciprocal teaching, and observing others learning (Stahl et al., 2014). In science learning, the collaborative supports can provide discussion boards, representational tools, or shared simulation space for learners, and can often take the form of scripts for students to guide effective interactions (Jeong et al., 2019). CSCL also has the potential to promote social interactions during reading activities. For example, elementary students participating in online collaborative readings with peers, improved reading comprehension when compared to individual reading (Vega et al., 2020), and scripted interactions between college students using an online CSCL tool enhanced their reading literacy in science content (Lee, 2015). While these technologies show promise, they require coordination between multiple learners, and therefore may not always be applied for reading activities at home and be difficult for younger learners to engage with outside of school.

In scenarios where human-human social interactions are difficult or not available, social robots have demonstrated a particularly powerful ability to make social connections with learners in ways that can improve learning (Belpaeme et al., 2018). Humans, especially children, seem to have reflexive and strong social responses to robots, where people apply and expect social norms during interactions (Ham et al., 2012). These strong social responses can be quite effective in learning environments, where robots build social connections with learners during activities (Michaelis & Mutlu, 2018), can provide meta-cognitive supports in stressful learning situations (Brown & Howard, 2014), and can inspire thinking and creativity (Gordon et al., 2015). The capacity for social robots to provide social interactions can be coupled with CSCL approaches to present socially situated learning supports. Social robots can effectively coordinate collaborative learning between human learners and can also act as collaborators themselves in learning interactions (Miyake & Okita, 2012). Social robots can act as less-able peers who need help from children to learn (Walker & Burleson, 2012), share in creating a story (Wong et al., 2016), or engage students in discussions about science (Shiomi et al., 2015). However, there is limited research on robots providing social interactions during reading activities, particularly for in-home settings.

In response to the need for work exploring the role of social robots for in-home learning, particularly as homework reading companions, we have begun a research program to explore the design of such a robot and understand the learner's experience during these socially interactive learning activities. Here we expand on findings from prior work to further our understanding of learning with a social robot during a shared science reading experience (Michaelis & Mutlu 2018, 2019). In this study, we ask the research question: *How do middle-school aged students experience learning while reading a science textbook with a social robot?*

Method

To explore the experience of reading with a social robot, we conducted a lab-based study where children read a science textbook chapter with "Minnie," a social robot programmed using design elements based on prior work (Michaelis & Mutlu, 2018). Here we report on the study procedure, materials, design of the robot's comments.

In a larger study, we recruited children from a mid-sized city in the Midwest for a randomized control trial testing the effectiveness of reading with a socially adept robot, compared to a robot without socially engaging features. Here, we examine the experience of the children in the socially-adept condition (N = 30). We chose to focus on this group since they received the maximized social interactions. Children in the study were aged 10-12 (18 male, 12 female) and had not yet started their 7th grade year. Study activities took place in a campus lab office after parent consent. Parents were compensated $25 USD for their child's participation, and study protocols were reviewed and approved by an institutional review board. Children completed a 30-minute reading session with the robot and were interviewed about their experience following the interaction. Several quantitative measures were also made during each session and are reported on elsewhere (Michaelis & Mutlu, 2019).

Minnie (See Figure 1, left) is based on an open-source 3D-printable tabletop robot, Maki, with servo-controlled head and eye movements (Hello Robo, 2020). We modified the Maki designs to add: a Rasperry Pi 3 microcontroller for enhanced computing power; a camera for image and facial recognition; and a seven-inch touchscreen display for user inputs. The robot's camera enables the use of facial recognition to track and look towards the child's face during reading, and to read scannable ID tags called AprilTags (APRIL Robotics Lab, 2020). The touchscreen display includes five buttons along the bottom, where children can select inputs for "yes" or "continue" (green button), "no" or "stop" (red button), "repeat" (blue button, "pause" (yellow button), and "help" (purple button; disabled for this study).

During the reading sessions, children read out-loud to the robot from a book with embedded AprilTags. When they encounter a tag, children hold the book to the robot's camera, and the robot responds with a pre-programmed *knowledge support comment*, that is a verbal utterance from the robot to highlight important material, summarize key points, make personal connections to the reading, or encourage children to complete activities in the book. The robot was designed to act as a *near-peer* that portrays an age and level of science understanding near the child's age and grade level. Therefore, the robot's comments were often framed as the robot wondering about a part of the book or summarizing its own understanding of what was just read. For example, after reading a section on diagramming forces, Minnie says, "Okay, I think I understand. Arrows show forces because the arrow points in the direction of the force, and a bigger arrow shows a stronger force."

Children begin by reading a custom-made introduction book that acclimates them to the reading process with the robot, and how to use the buttons and AprilTags while reading. After the introductory book, children are then asked to read a thirteen-page section, titled *The Nature of Forces*, in a middle-school level science textbook (Padilla et al., 2005) with content covering balanced and unbalanced forces and types of forces such as friction and gravity. We chose this book because it is at a reading level appropriate for our samples' age group and covers science related material typically encountered in 8th grade in U.S. middle school that our sample would likely not be overly familiar with. There were ten AprilTags placed in the reading with unique robot knowledge support comments that resulted from scanning each tag. Two of the tags were placed near two activities included in the book, and when scanned, the robot invited the child to complete the activity and say what they observed happening and why they think it happened. The first activity, the *at-home activity* had the child balance two playing cards against each other so they would stand, as in a house of cards, then exert a force on one of the cards, and explain the role of unbalanced forces in what happened. The second activity, the *discover activity* (See Figure 1) instructed children to push two different sized stacks of quarters off their table at the same time to observe which falls faster. Both stacks should fall at the same rate, and to ensure children saw this clearly, the robot is programmed to comment after the activity that both stacks of quarters fell at the same time. All activity materials were provided for the child, and they were allowed to complete the activity as they saw best.

Interviews (10-15 minutes in duration) were completed after the robot interaction, followed a semi-structure qualitative interview protocol (Blandford, 2013), were video recorded, and later transcribed verbatim. We then conducted a Thematic Analysis to analyze the data (Braun et al., 2018). Two researchers, including the first author, first familiarized themselves with the data where they reviewed and created notes from the videos. We then generated semantic codes closely related to the data using an inductive approach and organized the data within major categories based on these codes, including supporting knowledge, supporting interest, and social interactions. From these categories we then iteratively proposed, constructed, and refined emergent themes based on meaningful patterns in the data. The findings below are presented according to these themes.

Results

After several rounds of thematic analysis, we found that children felt the robot supported their learning and improved the depth of their understanding along three major themes, where the robot: (1) helped them slow down and focus on the reading, (2) provided summaries and guided attention to important parts, and (3) worked with them on the activities. Each theme is described below with quotes from participant interviews using participant IDs (e.g. R34). For clarity in reading quotes, ellipses were added to connect ideas in the responses, bracketed words indicate intended objects, and interjections were removed when not impacting the meaning.

Theme 1: Children slowed down their reading and focused more

Children felt that reading with the robot made them slow down and focus more on their reading in ways that helped them think more deeply about the content of the book chapter. In particular, children told us that reading to the robot helped them to slow down and focus so they could: (1) help the robot understand the content, and (2) think more deeply about what they read since they knew the robot would comment about it.

Children often said they learned more from reading out loud with the robot, because it slowed them down, and that slowdown helped them feel more focused on the reading. Most children directly related slowing down and focusing to the presence of the robot, as R36 told us, "If you were just reading aloud to yourself you might kind of slip over everything and say it fast." The idea of ordinarily skimming through textbook readings was brought up by several other children. For example, R2 told us that without the robot they “sometimes might skip a line”, R50 said “if I was reading it on my own I might have skimmed it and skipped over some important things,” and R64 told us, “when I’m reading alone, I normally just pretty much skim the concept.” Slowing down and not skimming the text was related to children feeling more focused on the reading. Children said the robot “focused me more” (R2), “helped [me] stay on task” (R10), helped them “concentrate” (R18), or that without the robot they “wouldn’t have paid much attention (R16).” R64 further explained that they didn’t skim with the robot, because, “if you’re reading to people, they would want you to slow down so I just kind of did that to the robot.”

These responses help us recognize that the robot’s presence and interactions seemed to drive children to read more slowly and focused in two ways. First, children told us they felt they should read clearly and thoughtfully so the robot could understand the content. For example, R64 said they slowed their reading down because they, “didn’t want to be confusing, and I wanted [the robot] to learn.” This slowing down for the benefit of the robot seemed to be linked to feeling that the robot was listening to them, as R50 illustrates by saying the robot is, “someone who seems like they are listening to you read it, so… it sort of depends on you that they can understand it.” Second, children seemed to anticipate the robot’s comments as a sort of query, that compelled them to spend more time focusing and thinking about what they read. Children felt they had to “think about what you were reading to respond to the robot (R14),” or that the “robot might ask me a question so I thought about it more (R16). Some children felt the robot would check on the child’s understanding, in ways that were also beneficial to the robot’s understanding – that the robot “sort of checked in for herself” (R50). Perceiving these interactions as ways to stop and think about what they were reading and to learn along with the robot appeared to drive a sense that they were understanding more, as R14 said it “makes you think deeper about the book.”

Theme 2: The robot provided summaries and guided attention

As part of the creation of our knowledge support comments, we intentionally created robot comments to correspond with challenging or important parts of the text, or that directed children to consider the figures and side-panels in the text that might otherwise be ignored. Almost every child in the study discussed these knowledge support comments as helpful for their understanding, and many suggested they felt the: (1) robot explained difficult ideas in the text, (2) comments often answered questions they had or gave them time to think about the reading, and (3) robot guided their attention to important parts of the reading.

Describing the robot comments as explanations or summaries was quite common. Children said the robot, “explains things you just read” (R4), “reviewed” (R28), gave a “reminder of what you just talked about (R48), “gave you a recap that sticks in your brain” (R20), or “makes sure you know and grasp the concept” (R64). Children revealed that they often faced challenges in understanding the concepts in the reading that the robot helped with, as R26 told us “I would read like two entire pages and then she’d say a quick summary and it helped me figure it out more easily, because sometimes I’d read this really in depth thing and then [feel] like ‘wait what just happened.’” R02 also added, “if I didn’t understand something, the robot would just break it down simply and that helped.” This was a very common response, where children felt that after reading the somewhat dense material in the textbook, they benefitted from the robot’s comments that explained the concepts.

They also felt that the robot’s knowledge support comments provided a summary or review of concepts that often served to answer questions they already had, or even “confirm your thinking was right (R10)”. R8 told us “it’s almost like you can ask questions, in a way, so it’s like she answers your questions.” R10 said, “sometimes it says something that you were kind of thinking in the back of your mind, but you weren’t really noticing it. And then [the robot] kind of helps you understand it a little better.” Through these explanations, the robot seemed to help clarify challenging ideas and bring the concepts to the forefront of their thinking. There was also evidence that children felt these knowledge support comments could either clarify or confirm their understanding and anticipate their questions, as R26 told us, “I had the question before the book asked the question, and I was like oh yeah I was thinking that too. And then [the robot] explains it.” Having the robot there to provide these supports appeared to be important to the children, as R44 summarized, “usually if something was hard in the book. . . you would have to figure it out by yourself but the robot… helped out.” There seemed to be something specifically important about the moment after each comment for the children to think about the material. They often described benefitting from thinking for a moment to absorb what the robot had said. R6 told us after the robot, “made a comment then [I] just paused and thought about what it said, and got more stuff,” and R8 said that when they were confused, “after a comment, you’re like ‘oh, hey, that’s how it works’.” R36 said, after a comment, “I thought about everything she said and then I could remember it more.” It appears that children experienced the robot comments not only as supportive information, but as targeted answers to questions and opportunities for thoughtful reflection.

Finally, some children suggested the comments guided their attention. R60 told us the, "robot pointed out things when they were saying something that I might have missed," and R58 felt the robot "pointed stuff out to me that I didn't really see." For R16 the robot drew their attention to figures in the book as ways of talking about real life examples. Specifically, R16 felt the robot used the example of racing reindeer in a book figure (See Figure 1, right) to explain how the "reindeer were a greater force than the friction, so they were moving." This comment from the robot was particularly helpful for the child since they had "just kind of glanced over [the figure], but then [the robot] mentioned it." R58 agreed that "the picture [of the reindeer] was a good example" of pointing things out. We were intentional in designing some of the robot comments to refer to figures in the book, and it seems that these references helped children who may have otherwise missed those pieces of the reading.

Theme 3: Working with the robot on book activities were powerful interactions

Another area where we deliberately designed comments to point out parts of the textbook reading to children, were the two activities contained in the book chapter. These seemed to be experienced by the children as opportunities to work with the robot on the content, and were appreciated as moments of interactive learning that they would have otherwise skipped – often resulting in powerful moments of understanding. Although the robot only made comments before and after the activities, children felt that these were interactive experiences. They felt that they were, "learning more," by "doing the tasks with [the robot] (R06)", and because they "actually have to interact with [the robot] (R64)." Doing these activities with the robot helped R14 "feel more involved." R64 said they had to "do little projects that you normally wouldn't do. . . you would talk to [the robot] and explain it." The notion that children might not ordinarily engage with the activities was also mentioned by R24, who said they "normally don't do the activities at home," but they "helped with being stumped." This interactivity appeared to help children feel they were working with someone else to make connections and think critically about the content in the text. R32 told us that when the robot's comment matched what they saw during the activity, they "understood it more and I felt like somebody else had the same opinion as me." The impact of these convergences of ideas was very clearly articulated by R20 in the following exchange about their experience doing the at-home activity in the book:

Researcher: I noticed that at the end of the book, when you started reading about air resistance. . . you said, 'Oh, that's why they fell at the same time,' and you went back, and kind of picked up the quarters and looked at them again. Can you tell me about that, like where that sort of connection came from?

R20: I thought that it was supposed to be connected because they did one and that [the quarters] fell at the same time and that they didn't do what I expected. It was, just mindblowing.

Researcher: Did you notice, did you see that they fell at the same time on your own? Or did you. . . because the robot also has a comment that sort of makes sure that you do see that they fall at the same time. Sometimes people sort of miss that. Did you figure that out on your own, or did the robot kind of help you see that, or did you remember that?

R20: I didn't and then I thought I did it wrong because you're not used to doing that, and so then I scanned the page and I did it one more time, I heard the robot's comment and then I'm like woah, that's actually what it's supposed to do and I'm like woah, that was mindblowing.

Here R20 demonstrates how they connected the comment the robot makes, explaining why objects with different masses fall at the same rate, to their experience with the at-home activity. The robot guided R20's understanding and strengthened this understanding with a later explanation. R20 described the robot making this connection as "mindblowing," that indicated help from the robot to connect ideas across the reading was very powerful. This exchange helps to summarize how children saw the benefit of their reading with the robot. The robot seemed to do more than simply provide supports for their reading, but rather provide a socially rich interaction.

Discussion

In this study, we sought to further our understanding of how children experience science learning with a reading companion robot. The results from our semi-structured interviews with children after reading with the robot demonstrate that the robot: (1) created a sense that the learning experience was for both the child and robot that helped focus the child's efforts; (2) provided targeted supports that anticipated the child's questions and guided their learning; and (3) participated in interactive knowledge building to help children think clearly and deeply about the content. Involving a social robot in science reading activities may be a powerful tool in re-imagining these reading activities as socially interactive rather than isolated. While there is evidence that children have strong social responses to robots (Ham et al., 2012) and that there are learning benefits to working with a robot (Belpaeme et al., 2018), there are currently no studies to examine how children experience reading science content with a robot. We believe evidence from our study suggests that the social presence of the robot transforms the reading experience into a shared knowledge building activity between the child and robot, that extends beyond the scripted knowledge support comments of the robot. Children found that the presence and demeanor of the robot encouraged them to utilize better reading habits (i.e. slowing down, focusing, and thinking) that benefitted their learning. They also described the reading as interactive, where they felt a constructive back and forth in grappling with the concepts in the book, particularly in completing the discovery and at-home activity in the book.

These findings provide a unique perspective on our understanding of child-robot learning interactions. To strengthen learning sciences theory, we provide demonstrate how children experience reading interactions with a robot, how knowledge can be co-created with an artificial partner, and how socially appropriate and meaningful interactions are key to creating powerful co-learning experiences. We believe our findings also illuminate practical implications for integrating these interactions into class and in-home learning experiences, and illustrate the aspects of the reading interactions that might best be leveraged for deepening science learning. Here, we discuss how our results support and expand prior work and share practical implications of science learning with a social robot.

Social robots provide socially rich experiences to scaffold and co-create knowledge

Empirical evidence from learning sciences research has demonstrated the benefits of social interactions during learning. Social interactions provide supports or scaffolds for learners that aid their understanding of concepts or that allow them to work on problems or material they might not otherwise be capable of doing alone (Vygotsky, 1978). Social engagement provides meaningful and natural interactions that promotes depth of thought about the content and builds deep and interconnected knowledge by co-constructing knowledge. The findings from this study demonstrate how the social presence of the robot directly and indirectly enhanced the learning experience.

Learning new concepts can be a tremendous task for novices, and these learners tend focus on the surface features and basic ideas they are grappling with, rather than complex or integrated knowledge we strive for in modern educational contexts. Our findings demonstrate that while children were reading the science textbook, they felt that their interactions with the robot allowed them to think more deeply and better understand what they read. For example, R10 told us the robot sometimes, “says something that you were kind of thinking in the back of your mind, but you weren’t really noticing it.” In this way, the robot’s comments helped children articulate and connect their ideas. While sharing this reading experience, children attended to new concepts, but often weren’t able to fully grasp the themes and bigger ideas of the reading. The robot provided summaries or pointed their attention to key aspects of the reading to aid their deeper thinking. The inability of learners to contend with the complexity of new content has been demonstrated in prior learning science research, and there is strong evidence that suggests learners benefit from social interactions in working on new material (Miyake & Kirschner, 2014). Our findings are in line with these theoretical perspectives, and add to this body of work, by demonstrating that children have a natural inclination to embrace a social robot as a near-peer, and that children feel these interactions are beneficial to their deeper understanding. Learning theory also suggests scaffolded supports can simplify or highlight connections and complexities within the content and relate new ideas to other knowledge and concepts (Puntambekar & Kolodner, 2005), We expand on this theory by demonstrating the benefit of providing these scaffolds in a social context. Our robot often used traditional scaffolding techniques, such as summarizing and guiding attention to a key figure, in a conversational way, within the social context of learning with the child. Scaffolds that summarized concepts were delivered as if the robot had just understood the material and was now summarizing their understanding, rather than presenting the summary as simply a fact for the child to absorb. We believe the robot’s social presence was key in providing direct supports for children.

The social presence of the robot also seemed to provide context for children to feel as if they were *learning with the robot*. Learning socially with the robot presented indirect benefits to the learning experience, where children slowed down their reading, focused more and read clearly so that they and the robot could better understand. At no point were children instructed to behave this way. Rather, our findings suggest these indirect effects came from children feeling that they were learning together with the robot, which seemed to cause them to subsequently change their typical reading habits to conform to the social context. This benefit is in line with prior work on the benefits of group learning to co-create knowledge (Miyake & Kirschner, 2014). One important element to induce the effect of learning together seemed to be that our robot’s personality was designed to be a near-peer (i.e. at just about the same ability level), rather than a tutor or teacher. Children felt the robot needed the child to help it learn, and wanted the child to think about the reading so the child could engage with the robot's comments (that were often seen as questions). That the robot could instill this sense of co-learning with such limited interactive capabilities demonstrates how willingly and naturally children embrace such a learning paradigm. We believe we provide evidence that the social presence of the robot had the indirect benefit of transforming the learning experience into a more meaningful and deep exchange of knowledge that stems from our natural ability to build on one anothers' ideas and work to achieve mutual understanding.

Practical implications: Augmenting learning using social robots

Our findings suggest that learning with a social robot can enhance the learning experience and transform a reading activity into a socially meaningful interaction. These findings have practical implications for learning with robots in both in-home and in-class settings, and offer some nuanced details of design and implementation decisions that can best facilitate the social learning experience. First, in creating direct learning supports, it appears that interactive activities interspersed throughout the reading may provide important learning opportunities, and also provide key moments for the robot to refer back to. Our reading included two such interactive activities, where children were asked to try balancing forces with playing cards (the at-home activity), and to observe the rate of falling for different masses with similar shapes (the discovery activity). In both of these activities, the robot asked the child to summarize their thinking and explain what they saw, which encourages the child to reason about these concepts. Since children often told us they would ordinarily skip these, the request from the robot seemed to be important to encourage them to engage in and think about the activity. The robot also referred back to these activities during the reading to help connect ideas, but also to enhance the importance of engaging in the activities. Second, the robot's design appeared to indirectly impact the learning experience by triggering social norms and expectations from children. The robot comments being interspersed throughout the reading seemed to emulate an interactive reading style that fostered the co-creation of knowledge, where children were compelled to focus, read carefully and take time to gather and synthesize their thoughts about the content. Our knowledge support comments did not deliberately ask children to slow down or think deeply, but there seemed to be an indirect effect of the social context that encouraged children to do so. The near-peer perspective of the robot may have enhanced this effect as children attributed the robot's need for understanding as a reason they read more carefully. We also found many children thought the robot anticipated their questions or was even asking them questions, as the robot provided comments that related closely to challenging aspects of the text. Our robot was not technically capable of such enhanced interactions, but the child still felt they needed to read more carefully to engage with the robot. These observations show how social supports enhance the experience, but improvements to the interactive capability of the robot, including asking and responding to questions may also be required.

In summary, based on our observations of the benefits to the student's learning experience, to promote deeper thinking while engaging in science reading we suggest designing robot interactions that: (1) provide opportunities for interactive activities during science reading, (2) allow time for the child's thoughtful reflection, (3) include robot references back to joint activities and previous learning, (4) utilize a near-peer perspective for the robot, and (5) closely tie robot comments to critical and complex parts of the reading. These supports can benefit in-class activities, where a robot might guide individuals or a small group, as well as in-home learning, where a robot can become a homework companion that encourages active engagement with content. The positive effects of these designs can be achieved with a relatively low-tech robot, but sustaining positive interactions over time may require enhanced capabilities such as posing and responding to questions.

Conclusion

In this study, we explore children's experience of reading with a social robot, and these experiences inform designing learning technologies. This approach limits the scope of our interpretation, in that we cannot report causal effects between these experiences and learning. We are also limited in that we do not include a comparison to other learning technologies or to reading on their own, and therefore cannot determine the scale of the effect of reading with a social robot. Finally, the short duration of the reading limits understanding how these interactions may change over time. For future work, we plan to examine science reading with a social robot in the context of school-based homework, over time and compared to other interactive learning technologies. During these studies we will conduct quantifiable measures of learning and estimates of changes in interest over time.

In summary, these findings demonstrate reading with a social robot creates a social learning experience that children feel encourages them to think deeply and engage meaningfully with science content. These findings support the growing belief that social robots can be a powerful tool for learning, and the social nature of the interactions can enhance student learning in tasks, such as reading, that may otherwise be isolated.

Distributed Argumentation for Politicization in an Activist Campaign

Joe Curnow, University of Manitoba, joe.curnow@umanitoba.ca

Abstract: The paper analyzes the emergent practice of *distributed argumentation* in an environmentalist campaign. I argue that distributed argumentation was a sense-making process spread across participants as they iteratively, interactively articulated political rationales, with speakers alternating and building on their colleague's contributions. This practice emerged as both a collaborative practice of intentionally supporting colleagues' concept development, as well as an oppositional practice that sought to combat more conservative colleagues by affirming peers they identified with and expanding on their argument. Theorizing distributed argumentation contributes to studies of democratic education and argumentation by exploring the interactional learning that happens beyond classrooms to build skill in engaging in democratic debate and politicization

Argument is a pervading activity as I write, with the ongoing public and private debates of US partisan politics, appropriate approaches to pandemic management, racial justice, climate change, and the list goes on. There is much to debate and, in North America (as elsewhere) an increasingly polarized context where finding common ground can seem nearly impossible, and often unpalatable. Yet in the learning sciences, discussions of debate and deliberation rarely reflect the kinds of real world intensity and consequences that many of us face in debate. In the literature, debate and discussion are highlighted as important aspects of democratic engagement, rather than as toxic spaces where some people's humanity is devalued. For the last years, I have worked as an activist scholar alongside the RadLab, a group of youth climate activist researchers, to understand the ways that sense is made around politics, and a recurring theme we encounter has been that of debate and argumentation—how it happens, who it serves, and how norms around expertise get reified and mobilized to undermine Black and/or Indigenous people and people of colour's (BIPOC) participation in environmentalist spaces, as well as that of white women, though differently. In this paper I seek to complicate ideas of argumentation, drawing on a non-school, activist context where young adults engaged in consequential argumentation, and I show how the argumentation practices evolved to address dominant masculine and white practices of power in the group. I argue that distributed argumentation was an emergent strategy that BIPOC and white women participants mobilized to make space for themselves and to enable their own politicization.

In this paper, I explore how activists engage in political concept development through argumentation. I ask what practices enabled student activists engaged in the Fossil Fuel Divestment Campaign at the University of Toronto. I examined the emergent practice of distributed argumentation, where participants in the campaign interlaced bids at argumentation with their colleagues in order to collaboratively develop political ideas. In distributed argumentation sequences, I examined activists' attempts to articulate an emergent politics without yet knowing what they were arguing, making connections on the fly, and building on their colleagues' ideas iteratively. I argue that distributed argumentation allowed participants to build on each other's ideas, build confidence, and expand their learning beyond what any participants might generate alone. I highlight how relationships of politicized trust made it possible for distributed argumentation to evolve as a practice, and how distributed argumentation built politicized trust and shared identity through politicization.

Context

Fossil Free UofT was a youth climate activist group that worked for over two years to get the University of Toronto to withdraw its endowment's holdings from the 200 fossil fuel companies with the largest fuel reserves. Student activists, including undergraduate and graduate students met weekly to plan outreach activities, to strategize around persuading the university administration, and to coordinate retreats, rallies, and other demonstrations to help them win their goals. In this campaign, a highly racialized and gendered pattern of turn-taking emerged (Curnow & Chan, 2016), where white men dominated the talk, and where these white men advanced a more conservative set of politics which centred technocratic analysis of climate change rather than anti-colonial and antiracist perspectives (Curnow, et al., 2019). Over the course of the campaign, these different political ideas and the turn-taking dynamics which made them difficult to override/challenge/contest became highly contentious ground, politicizing many members of the group and polarizing the dynamics.

As the group became increasingly polarized, two strategies emerged which enabled white women and BIPOC members of all genders to disrupt the turn-taking. First, they organized formal and informal meeting spaces outside of the large group meetings (Curnow, et al., 2020). This created space for them to debrief the dynamics of the large group and to create their own norms around participation, where their voices were heard and acknowledged, and their political development was fostered. Second, they innovated with practices which made it harder for a few white men to dominate discussion (Curnow, et al., 2019). It is these practices of resistance that I examine here, to see how they emerged, what they enabled, and how they contributed to the politicization of non-dominant participants. These approaches to argumentation extend the literature on debate and argument, in that they highlight an emergent practice of argumentation that worked against the marginalization of BIPOC and white women speakers, and which extended the political analysis that was being centred in the discussions.

Perspectives

To understand the phenomena of distributed argumentation, I look to work on argumentation and sense-making in the learning sciences. Studies of democratic education have argued that debate and argumentation are a core practice of democracy that can be learned and practiced in schools (Mirza & Perret-Clermont, 2009). These studies often examine teachers introducing artificial debate and managing student participation. In recent years, learning scientists have examined argumentation practices among school children, arguing for sociocultural analysis that attend to participation in debate (Asterhan & Schwarz, 2016; Kolikant & Pollack, 2009), and suggesting that argumentation practices are necessary for students to expand their learning into critical analysis (Schwarz, et al., 2016). Little has been written to explore how democratic debate learning among adults, or how argumentation links to political development, and so our work extends the school-based literature, challenging the boundaries of teacher-structured debate. My work looks at the consequentiality of argumentation when the stakes are real and highly salient, particularly for non-dominant participants from BIPOC communities, the queer community, etc.

To contextualize argumentation within relations of power and politics, I look to the expanding learning sciences research oriented to questions of how learning is always already political (Politics of Learning Collective, McKinney de Roysten & Sengupta-Irving, 2020), as well as how people learn politics (Curnow, Davis & Asher, 2019; Philip, et al. 2017, Vea, 2020), become activists (Curnow 2013r; Kirshner, 2008; Uttamchandani, 2020), and create change at scale (Jurow & Shea, 2015). This work makes clear that learning ecologies, including argumentation spaces, are not neutral, but are embedded in the dominant relations of our societies, and that "our theories of learning are theories of society" (Philip & Sengupta, 2020). Through this lens, scholars have to attend to the ways that dominant social relations shape the field of learning and the practices that unfold within them, and problematize the ways that they are implicated in the reproduction of inequality.

In this context, the RadLab has examined the longitudinal and micro-interactional practices through which activists become politicized—shifting their political analysis, their ways of knowing, their practices, and their identities (Curnow, Davis & Asher, 2019) and attending to the ways that sociohistoric relations of difference, including racialization, gender, and class, shape who becomes politicized in under which conditions. Our analysis of distributed argumentation carries that work forward, examining the micro-interactional practices that created space for some activists to develop new orientations to radical politics.

In addition to our work on politicization which helps us to theorize the interrelated learning process that unfolded within FossilFree UofT, I also look to recent work on politicized trust (Vakil & McKinney de Roysten, 2019; Vakil, et al. 2016) relations of confianza (Teeters & Jurow, 2018), and educational intimacy (Uttamchandani, 2020). In different ways, these papers highlight how spaces of solidarity are constructed and enable politicized learning among non-dominant participants. These papers stress the agency of non-dominant learners, as well as the significance of trust rooted in a shared experience and analysis of dominant power relationships in making space for resistance, resilience, and revolution. These relationships of solidarity were also scaffolded through processes of guided emotion participation (Vea, 2020), where the emotion practices of participants shaped the sense-making among BIPOC and white women participants, as their feelings were simultaneously shaped the sense-that-was made of relations in the group (Curnow & Vea, 2020). This work lays out the importance of relationality, solidarity, and shared emotional sense-making in the context of contentious politics, and enables us to analyze the ways that distributed argumentation practices relied on and built politicized trust through shared emotional and politicizing processes.

For studies of argumentation, centring politicization, politicized trust, and emotionality in the context of sociohistoric relations of power recentres our analysis away from ideas that debate and deliberation are neutral, social goods, and helps us to instead see how argumentation strategies can enable political learning, but at a cost.

Methods

This project emerges from a long-term collaboration with youth climate activists involved in Fossil Fuel Divestment. Through a participant action research process (Maguire, 1987), the RadLab asked questions about when and how environmental activists became radicalized around racial and gender justice. Orienting to militant ethnographic principles (Scheper-Hughes, 1995), our team is made up of activists from the group, who collectively designed questions, analyzed the video data, and wrote up findings. The strength of this approach is in our deep relationship to the context, where our immersion in the group allowed for activist researchers to theorize the consequentiality of distributed argumentation in alternative spaces and how they travelled to the meetings, and then rely on video data to evaluate the extent to which the pattern was sustained in the data, and if/how it changed the dynamics of Fossil Free UofT.

We analyzed this process of emergent distributed argumentation within the context of a campus-based environmentalist campaign as part of a larger project analyzing politicization processes. From September 2014 to April 2016, Fossil Free UofT met weekly to plan events and coordinate strategy. Meetings lasted two to three hours, with facilitation responsibilities rotating between members. Participants engaged in activist work on campus, including recruiting, event planning, coordinating rallies, and meeting with the administration. Many students came into the organization as a-political or as moderate, yet many became politicized through their engagement.

Through interaction analysis of over 10,000 minutes of multi-camera video data (Derry, et al., 2010; Heath, Hindmarsh & Luff, 2010) of large group meetings, actions, and the Women's Caucus, as well as Stimulated Recall Interviews (SRIs) (Dookie, 2015; Lyle, 2003), we examined different practices that supported political concept development. After content-logging and preliminary coding, our participatory action research team collectively iteratively coded for interaction (Jordan & Henderson, 1995; Angelillo, Rogoff, & Chavajay, 2007). We identified conflict, naming, jumping scale, and distributed argumentation as recurring themes in our data that enabled participants to participate in argumentation around radical politics. We then coded video from the most contentious meetings which we identified through a collaboratively constructed and coded timeline, identified by focal participants as generative and politicizing, for instances of these codes. Two aspects of distributed argumentation became salient, those behind the scenes, and those we traced in coding the videos of conflict. In addition to content logging and coding, we also transcribed subsets of the data, which are excerpted here. Because the phenomena of distributed argumentation is often spread over significant amounts of talk, these transcripts are not shared in full here, but are paraphrased and then highlighted to identify the kinds of convergence we found through distributed argumentation. To analyze the learning behind the scenes, which was often not recorded, we draw on field notes, SRI content, and journals from the time. While RadLab members jointly analyzed the data and co-drafted earlier versions of writing on distributed argumentation, they were unavailable to co-author this paper, but have been shared on drafts and provided feedback on the presentation of data, which has been integrated as part of the process of member checking and relational accountability.

Findings

In this section I outline two distinct, but related, practices of argumentation.. In the first, distributed argumentation occurred in spaces outside the main meetings, especially the women's caucus, people of colour caucus, and the equity committee. These spaces were more politically radical, but also did not include campaign members who opposed radical political ideas, thus these spaces allowed for a different environment for developing ideas. In the alternative spaces, we see equity-oriented participants collaboratively construct arguments. Participants extended their own learning by building on arguments that were still embryonic, based on their sense of allegiance and identity. In the second, we see this practice travel to the large group, but shift purposes; rather than intentionally helping participants to articulate concepts for themselves and others, the distributed argumentation practices in the large group was a strategy of disrupting toxic argumentation practices, resisting domination, and contesting dominant, and more conservative, narratives. In this context, distributed argumentation was used to contest the opposition and to build on arguments that were emergent. We saw distributed argumentation emerge as a strategic intervention that allowed people of colour and women to vocalize their experiences of marginalization in the Fossil Free UofT meeting. Where participants said that the first context felt more comfortable and invited them to explore and develop ideas, the second context served a similar purpose, putting participants in a defensive position in which they built on others ideas based on identity and alignment. In our analysis, RadLab members identified these practices as related, where the alternative space collaboration enabled them to develop the muscle of iterating on each others' ideas based in trust and identity, and they credited those spaces with enabling the contestation and learning in-real-time that unfolded in the large group.Through both contexts we see distributed argumentation opening up and expanding new political concepts and reshaping activists' engagement with radical politics.

Alternative spaces

As space was foreclosed across the large group meetings, BIPOC members and some white women increasingly sought and created "alternative spaces" for themselves, where their ideas could be heard and developed in a supportive, rather than combative space, and where an environment of solidarity and politicized trust emerged. distributed argumentation in these settings is very much about individual participants being encouraged to articulate political ideas for themselves, and for others. It has both a sense of talking it through for oneself (in some instances) and a pedagogical feeling of modeling for others. In some of the instances, the talk here is doing the piecing together—sensemaking in real time. And it is affirmation seeking, and responds (in most, but not all cases) to the feedback, correction, and sculpting of other speakers— we can see how the ideas become shared products, and how they emerge again in later meetings and talk.

In the Women's Caucus, where women met to discuss their shared experiences of gender, the kind of collaborative sense-making that underpinned distributed argumentation flourished. We see instances of distributed argumentation as participants named the problematic turn taking dynamics (Curnow, et al., 2020), as they identified emotional labour as a gendered phenomenon (Curnow & Vea, 2020), and as participants linked experiences of gendered marginalization to other sociohistoric forms of oppression. For example, when presented with the initial data around turn-taking, the sense-making unfolded in real time:

Tresanne:	A lot of like- it was really sad to read all the things that I know. But then, but then to read it all together…
Lila:	[…] It's weird because at the time I didn't think of those things as problematic, at all. Part of that was that it was earlier, so I wasn't thinking critically about it. […]
Sydney:	I catch the blatant things, but not everything,
Heather:	I don't have much experience, but I thought [the turn-taking report] was really interesting, I'd never seen gendered conversation quantified, so I was kinda like, whoooaaa. And now looking for it, I've been looking around more, which is cool.
Jody:	Through the process of writing, I kinda felt like it was validating, like internal feelings, where otherwise I have a tendency to be like, oh maybe I was like looking for it and projected things that weren't actually there, or maybe I'm being too, like, I don't know what the word is. But like questioning myself, questioning whatever my feelings are, like feeling dismissed, or feeling invisible, so like that was kinda nice, in like a twisted way. Like, oh, it's nice, I really am, I really do never participate, and I think I don't. And also the fact that it was really messed up. It was worse than I expected, but also not surprising?

This exchange reflects a number of key practices in the alternative spaces. First, we see widespread engagement, in ways that are unique from the large group spaces. In this instance both Jody and Heather speak, which almost never happens in the large group, and which we interpret as an indication of some level of trust/comfort, or at least space to do so which is unique from regular meetings. Second, we see participants building on each other's ideas, and in the larger context that this is excerpted from (for space), we see consistent cross-referencing each others' contributions. We also see the kind of real–time sense-making as they collectively construct grievances around the gendered turn-taking practices, and begin to identify their own experiences as valid sources of knowledge which they had often dismissed (or had dismissed by others). In the larger transcript, we see this shared experience building a sense of camaraderie, and creating an environment that was filled with enthusiasm and, in some spaces, joy (Curnow, et al. 2020), where the sense of shared marginalization and the de-individualization of their marginalization created the kind of politicized trust that enabled them to build on one another's ideas, to joke and tease, and to push each other into deeper forms of cognitive analysis.

In another instance of distributed argumentation in alternative spaces, Lila reflected on her learning and planning process as she and Sinead designed a workshop on the root causes of climate change for the retreat in spring of year 2. Their planning came amidst two related processes that made the process significant: first, Lila and Sinead, and the other Equity committee members increasingly saw themselves as radical, and while many of the cognitive analytic links between colonialism, capitalism, patriarchy, and the environment were not yet clear to them, they spent significant time trying to read and theorize those links together, and they trusted they were there. Second, the large group was increasingly polarized, and Lila and Sinead envisioned the workshop as an opportunity to convince the more conservative members of the group through an evidence-based, well-facilitated process. In the planning process, Lila and Sinead spent hours designing a process meant to uncover the layers of interconnection between racialization, settler colonialism, and climate justice (something that had been litigated in the group in fleeting ways for over a year, but never been intentionally explained). In a journal reflection as part of the RadLab writing process, Lila reflected

> Thinking through things with Sinéad was a lot better than just thinking it through by myself because we were able to answer each other's questions and push back on things that we got to too fast, and make sure that we really had a good grasp on it. It wasn't distributed argument the way it was in larger groups, because there were only two of us, and we had more time to go back and revise, but it was still really good to like build the argument together. It helped me fill in the gaps in my explanation so I felt more confident believing this and explaining it to other people.

This kind of collaborative work was more common in the Equity Committee spaces, but not in the large group, and played a role in extending the cognitive analysis of climate justice that Lila and Sinéad were working toward, but had not articulated for themselves, or been in spaces where those critiques were made explicit. Lila describes how when one person made a statement and received push back they would try to build on each others' ideas and defend the position, even when they weren't confident about the specific logic. In this way, their planning process enabled them to extend the argument they were attempting to make around the dialectical relationships between race, colonialism, and climate change, building their own capacity to articulate the politics, and then also discovering a logic, making it more scientific, rather than an intuitive thing that they trusted but did not feel that they could explain publicly or go to bat for in the conflictual spaces of the large group meetings. Neither Lila nor Sinead was more capable and positioned as a mentor or teacher; instead they oriented to each other as resources and accomplices in their purposeful work as they collaboratively built something new to both of them. This collaboration space was an important space for cognition, but it's important to note that it was only available to them because the identity pieces were already in place—they already believed that there were core connections within the political analysis that they just needed to unpack. They assumed they were there, that they were correct, and that the two of them were capable of theorizing those relations and teaching them to the larger group through a shared process.

Throughout these alternative spaces, we see relations of politicized trust forming in real time and shaping the sense that was made of the dynamics in the large group. Distributed argumentation advanced this process by creating space for participants to work through their ideas-in-process. As Lila noted, the collaboration between herself and Sinead enabled them to extend their thinking beyond what either was individually capable of. It also created a sense of solidarity in the shared project of articulating a politics and in being ready to share that with the larger group.

Travel to large group meetings

Distributed argumentation looked quite different in the large group settings, where because a few white men spoke so frequently, it was deployed as a resistance strategy, an educational strategy, and an expression of politicized trust between equity committee members. In these spaces, distributed argumentation was identified as multiple turns spread across speakers which built on previous speakers. These turns almost always alternated with one of the dominant white men speakers' turns (ie: Amil (equity speaker), Graham (non-equity speaker), Lila (equity speaker), Graham, Sydney (equity speaker). In these conflict-oriented settings where turn-taking dynamics skewed toward a few white men who dominated the talk and argued for more conservative politics, distributed argumentation emerged as a practice of disruption and validation. It seemed to emerge as a way of backing other speakers up, affirming them. Often we saw interesting things happen in these turns where embryonic ideas got adopted by other speakers, and got expanded by different speakers in the process. This is one of the organic sense-making that we found in the data set of people talking through and making connections, and our interpretation is that this was driven by allegiance and also politicized trust.

In a September 2015 meeting, we see an interesting expression of distributed argumentation. The context of the debate was that in response to the brief submitted to the university president, FFUofT received a casual request to define "social injury", the defining criteria for divesting according to the university policy, more narrowly, and in relationship to other divestment campaigns on campus (Black Liberation Collective's campaign to divest from US private prisons and the Boycott, Divest, and Sanction campaign against Israeli apartheid). This argument unfolded over 40 minutes (because of the length, transcript is not provided here), pivoting around the questions of: 1. If climate change represented a more serious social injury than racialized and settler colonial harm in the other campaigns and 2. If FFUofT should do the "dirty work" for the university in establishing why our campaign was more deserving than the others. In this instance, we see the normalized patterns of speaking hold, with 11 minutes of talk spread out between three white men. After a brief interruption, we then see another 10 minutes of discussion by the same 3 white men. At this point, Lila interrupted the exclusive talk and asked for a go-around where all meeting participants could speak. What ensued was a discussion that hinged on larger contestation about the role of fossil fuel divestment as a campaign, and the tactics of the environmental movement more broadly. While the 3 white men who speak most frequently argue for a narrowly-framed approach to divestment and social injury, we see a series of BIPOC speakers and white women speakers who try to reframe against, arguing that solidarity with other campaigns should be the goal. The full transcript shows the interventions that are made in response to the white men speakers, but in the interest of space, because these turns are relatively long, I highlight here a selection of the responses which demonstrate the subsequent building on previous equity speakers' ideas..

Sydney: It's super important- like if we accomplish our goals, while disadvantaging other movements, I don't think we're actually accomplishing anything. I think it's really important the way that we frame this and the way that we- and the way we present our arguments, is not that ours is the exception. Because I think that, y'know what I'm saying? I think that if anything, we should be showing solidarity with other movements that are trying to work on divestment. (Minute 68)

Amil: My thinking are along the same lines of Sydney and Lila, I really don't want to handicap other campaigns. I know this is how, sort of , legal cases play out, but I'm not into law at all, and I just think that, ethically or morally speaking, saying that you don't want to divest from, sort of like, these shitty institutions because it will open the door to divesting from other shitty institutions, is a messed up argument to make. (Minute 74)

Jade: I agree. I don't want to shut anyone else down. I think there's a way of wording things where we can make our argument sound very convincing without being like, look how different we are, compared to other things happening now. (Minute 75)

Cricket: Building on what these people said, fossil fuel divestment only matters to a small number of people on this campus. UofT is not a very sustainable university compared to UBC where there's an institutional commitment to sustainability. Divestment is just a small drop in the bucket. And I don't think, for lack of another word, trampling on another campaign to get ours up, in the bigger picture, will accomplish much more for this campaign. Even if UofT does divest, there's still miles and miles and miles to go, and I don't want to see this campaign… which in the bigger picture, when it's just a small drop in the bucket, achieve its goals by putting another group down, cuz at the end of the day, our work is not the end of what UofT needs to do. (Minute 87)

Across these turns, speakers make a number of moves that are significant. They are consistently cross referencing each others' talk—other speakers cite other equity speakers, saying "Just going off what Sydney said…", and I agree with what was just said", and "building on what these people said…". They also use the same language-- the idea of not "handicapping other campaigns" comes up repeatedly by three different speakers subsequent to Amil's use. There's a travel of the major idea of solidarity and contestation of the idea that fossil fuel divestment is the most important issue on campus, and travel of the idea that justice work is linked. For members like Cricket, who was relatively new, this is a significant moment in articulating fossil fuel divestment in the context of larger movements for social and environmental justice.

A few aspects of distributed argumentation stand out here: first, we notice the diversity of participation (with 15 people speaking, including 10 BIPOC and white women) in comparison to the exclusive talk between three white men speakers making frequent and long turns. Second, we note the ways in which ideas of solidarity are being expanded in real time, by different people, as a way of contesting the white men's assertions. The idea of solidarity travels across speakers and expands into new directions of argument that attend to the assertions of the white men, but which also attempt to reframe the debate. Third, we can see how the relations of trust and identity emerge in this series. The sides of the debate are clearly delineated, and when BIPOC speakers and white women speakers take their turns, they orient to the substance of previous BIPOC & white women speakers. In some cases they explicitly bridge, while in other instances the bridging is suggested through similar discourse or extending the previous argument to respond to the critiques directed at that person. Even when this bridging does not happen, we interpret the continued turns in favour of similar ideas as a reflection of a shared politics rooted in politicized trust: they are extending each others' arguments as an expression of faith in their colleagues' analysis, as well as of identity.

Other examples from our data set include extended turns where, for the first time in the large group, BIPOC people named the racialized dynamics that were normalized in the group. Over a series of turns spread out across multiple speakers during a go-around where each speaker had a turn, BIPOC participants built on each others' contributions and extended the critique that the Women's Caucus centred, through which gender was the primary lens of analyzing the participation dynamics in the group. The sequence of distributed argumentation drew speakers in who almost never spoke in the large group, and explained the racialized marginalization that they experience in the group on the regular. We saw a similar phenomena when the Women's Caucus brought their concerns to the large group meeting. Spread across a group of women, we saw consecutive contributions which built on the contributions of colleagues and anticipated the critiques white men would bring to bear (see Curnow, et al, 2020).

Significance

Our analysis shows ways that activists were collectively engaging in sense-making practices, and moves discussions of democratic education and learning beyond the classroom and the controlled context of teacher-moderated debate. We show how activists learned to take up the ideas of colleagues and extend them, contributing to studies of learning in social movements, and contributing to new theorizations of political learning. This work is significant micro-interactionally and politically for the field of the learning sciences.

Micro-interactionally, this study reveals useful patterns around how embryonic politicization was fostered through turn-taking dynamics which required speakers to extend their learning beyond what had been articulated and fully made sense of in the moment as a way of asserting identity claims and contesting what were understood as racist, colonial, homophobic, and misogynist claims. This reveals an interesting process of sense-making in moment to moment interaction, where cognition followed the identity and epistemological development of participants, and was made possible through emergent practices designed to reclaim space. This complements Vygotskian work on sense-making, while drawing our attention to the ways that identity can be a central driver in which peers are oriented to as more-knowledgeable others, which ideas are extended as valuable and relevant contributions, and when these ideas and practices will be advanced by learners as they navigate new political terrain.

This analysis shifts the attention of work on argumentation, looking at the real world debates that are extremely common in today's contentious political field. This matters because it helps learning scientists to theorize ways that non-dominant people strategize and practice resistance in debates which too often de-legitimize and discount their existence. Too much of the scholarly debate around argumentation treats the parties of debate as false equivalents, where it is desirable, or at least permissible, for both sides of the debate to receive air time and be heard, acknowledged, and learned from (Sfard, 2020). This argument is dangerous and detrimental to the well-being of non-dominant participants, who are so often forced to engage with ideas, practices, and ways of knowing and being that fundamentally undermine and seek to degrade their humanity, their civil and human rights, and their ability to participate fully in the world. Rather than accept the norms of democratic debate un-problematically, this analysis shows the agentic interventions that radical activists coordinated collectively to resist and undermine their de-humanization and] assert agency, grow their political analysis, and shift the overall politics of the community of practice.

Adapting a Choice-based STEAM Learning Program to Remote Learning: Barriers, Competing Priorities, and Design Considerations

Kay E. Ramey, Reed Stevens
kay.ramey@northwestern.edu, reed-stevens@northwestern.edu
Northwestern University

Abstract: In response to the outbreak of COVID-19, schools and educational designers have been forced to adapt quickly to remote or hybrid instruction. This presents us with a critical need and unique opportunity to understand how to adapt teaching and learning to a remote format, the barriers and competing priorities that educators and designers have experienced in attempting this adaptation, and the impact that these adaptations have had on student experiences. Here, we examine these questions in the context of one choice-based, interest-driven STEAM (science, technology, engineering, arts, and math) learning program called FUSE Studios, by examining survey and interview data collected with educators and students who participated in this program remotely during Spring 2020. We also discuss design iterations our team implemented, in response to research findings.

Introduction

In response to the outbreak of COVID-19, schools and educational designers have been forced to adapt quickly to remote or hybrid instruction. It is unclear how long this will last and what long-term impact it will have on K-12 teaching and learning. This presents us with a critical need to understand how to adapt teaching and learning to a remote format. It also presents us with a unique opportunity to understand the barriers and competing priorities that educators and designers have experienced in attempting this adaptation. In this paper we investigate these issues by drawing on remote interviews conducted during Spring 2020 with teachers and students participating in a choice-based, interest-driven STEAM (science, technology, engineering, arts, and math) learning program called FUSE Studios (Stevens et al., 2016). We also describe professional development and design iterations that the FUSE team enacted in response to the data we collected with teachers and students.

FUSE is typically an in-person learning experience in which students choose STEAM challenges of interest. While the menu of challenges and challenge instructions is housed on the FUSE website, students complete challenges collaboratively in a classroom, using a suite of digital and tangible tools. As a result, our prior research has shown in-person FUSE to be an engaging experience for students (Stevens & Ramey, 2020) that helps them explore and cultivate STEAM interests (Ramey & Stevens, 2019). However, this research has also shown that peer helping and collaboration over shared materials and representations are core features of the FUSE experience (e.g., Stevens et al., 2016). This Spring, as schools went remote, this left us with open questions regarding how or whether FUSE would be adaptable to a remote learning context. On the one hand, we might expect that FUSE challenges being housed on a website would make them easily accessible at home. Similarly, FUSE being choice- and interest-based might make it well-suited to students working at home, where interest and motivation are typically allowed to and therefore play a larger role in engagement and learning than they do within classrooms (e.g., Ito et al., 2010). On the other hand, it was unclear whether the collaboration and sense of community we've observed in in-person FUSE studios could be replicated (or even approximated) in a remote context. Similarly, while many of the FUSE challenges use free, web-based applications or materials that students would have access to at home (paper, cardboard, spaghetti, marshmallows), other challenges require technology tools, such as 3D printers and breadboards that would likely not be available during remote instruction, thus limiting the number and types of FUSE challenges that students could choose to work on.

Consequently, we launched an investigation into how teachers were adapting FUSE to remote learning and what aspects of it were being retained or lost as a result of this adaptation. We focused this investigation on three specific research questions: (1) 'How have educators adapted FUSE to remote learning?'; (2) 'What barriers and competing priorities have they experienced in doing so?'; and (3) 'What impact have these adaptations had on student experiences?' This investigation was part of a larger inquiry into the ways in which our education partners have adapted FUSE (and the effect of those adaptations on students' experiences), as the program has scaled up from a handful of after school programs in one suburban Midwestern school district, in 2012, to over 200, primarily in-school implementations across the United States, in 2020. Therefore, our findings will also speak to the larger question of how/whether educators adopt and adapt educational innovations, particularly in times of crisis, and how educational designers might adapt to educators' needs.

Reasoning and innovation in times of crisis

One body of literature that informed our investigation of the ways in which educators did or did not adapt FUSE to a remote learning context was studies of reasoning and the fate of innovations in times of crisis. For example, in an experimental, decision-making study, Ben Zur and Breznitz (1981) found that when put under time-pressure, individuals tended toward conservative rather than risky choices. Similarly, research on business innovations suggests that during times of crisis (i.e., economic recessions or depressions), new or persistent innovation is the exception rather than the rule (e.g., Antonioli & Montresor, 2018; Holl & Rama, 2016).

Therefore, we might expect that, given the stress that the global pandemic put on educators (and everyone else), educational innovations might be deprioritized, and adaptations might be modest and limited to things viewed as essential. This would be consistent with narratives of remote learning during Spring 2020 as a poor approximation of school-based learning (Hobbs & Hawkins, 2020; Jacobson, 2020), rather than an experience which took advantage of this unique moment to reimagine what teaching and learning could and should be. But it also raises the question of what *was* adapted and how, as well as what reasons or motivations led to those adaptations. For example, did educators react to this stressful time by falling back on familiar or comfortable patterns of behavior or did they feel pressure to rapidly adapt or innovate to meet the new demands of remote teaching? If the latter, what types of adaptations did they focus on and why? These questions are important to answer, as they will inform our understandings of what is likely or possible during future periods of crisis.

Conceptual framework

In framing our investigation, we drew on prior work studying educational leadership, policy, and innovation from a distributed perspective (e.g., Fenwick, 2011; Spillane, 2006; Stevens et al., 2018). We conceptualize schools as distributed assemblies of people and things, and therefore, argue that understanding how such organizations adapt to new circumstances involves understanding how individual human and nonhuman actors come into and out of association with one another over time, forming and reforming different networks (e.g., Latour, 2005).

We further drew on work by Coburn (2001), which emphasizes the importance of examining how educators make sense of programs or policies, in order to understand how they are adapted and implemented. We believe that this perspective is particularly important to understanding remote learning adaptations that took place during Spring 2020, as teachers were required to make sense of and implement a series of rapidly changing policies, often without thoughtful, comprehensive, top-down guidance. As a result, we suspect that teachers may have had more agency than usual in interpreting policy and adapting (or not) their own teaching practice.

Finally, in working with our partner educators to adapt FUSE to their remote teaching needs, we drew on design-based research (Design-Based Research Collective, 2003) and design-based implementation research approaches (Penuel, Fishman, Cheng, & Sabelli, 2011). These approaches shaped our framing of implementation as an integral part of design, not a phase that follows it, and drove us to be responsive in using the data we collected to design new challenges, web tools, and professional development to support educators and students.

Methods

To examine how FUSE students and teachers have adapted to remote learning and what challenges or successes they have experienced in doing so, we collected three types of data. First, we sent out a survey in late March to all our partner schools to find out how and whether they were implementing FUSE during Spring 2020. We received responses from 43 of our partner schools. Second, we followed up with partners at nine focal schools where we had previously conducted interviews and observations, as part of our broader study of the spread of FUSE. We chose to focus on these schools, because we had the most complete understanding of what they were adapting from, as they moved into remote instruction. With our partner teachers and/or administrators at these focal schools, we conducted remote, semi-structured interviews via videoconference. These interviews focused on understanding whether and how they were adapting FUSE specifically and instruction generally to remote learning and any successes or challenges they'd experienced in doing so. We also conducted remote, semi-structured interviews via videoconference with four focal students at one of our case study schools. These students were selected in collaboration with our partner teacher at that school, in order to represent a cross-section of student perspectives and experiences on FUSE and remote learning. The interviews focused both on how students were experiencing remote instruction broadly and specifically on their experiences doing FUSE remotely.

Findings

Survey responses and interviews with educators at our partner schools showed that many of them were using FUSE during the period of remote instruction and also adapting it in a variety of ways. For example, of the 43 survey responses we received, partners at 13 schools reported that they were still offering FUSE as a required course remotely. Another 25 reported that FUSE participation was optional for students. Only two said that FUSE wasn't being offered at all, and two said that they hadn't decided yet. In describing the format of instruction, 26 school partners reported that FUSE and other classes were being offered asynchronously, 2 reported that they would be engaging students in synchronous instruction, and 13 reported that they would be doing both.

Our interviews with school partners provided a more detailed picture of adaptations, as well as the barriers and competing priorities educators were responding to in adapting FUSE. For example, through iterative rounds of inductive coding, we identified two specific barriers that educators (and students) experienced: (1) access to technology; and (2) competing home and school interests and responsibilities. In attempting to adapt FUSE to overcome these barriers, our partner educators also described being faced with competing priorities. The three sets of competing priorities that we identified were: (1) foregrounding required subject matter content versus foregrounding student engagement, (2) prioritizing choice versus prioritizing accountability, and (3) promoting online safety versus promoting unrestricted, open collaboration. Sometimes these competing priorities were both held by the same individual (e.g., the FUSE teacher), who had to figure out how to balance them in adapting to remote instruction. Other times, they were held by different individuals at different organizational levels (e.g., the FUSE teacher vs. building or district level administrators). However, in all cases, we argue that how teachers navigated these competing priorities decisively shaped both how they adapted FUSE to remote learning and how students experienced FUSE remotely. In the sections that follow, we will discuss each barrier and set of competing priorities in greater detail. We will then close by explaining how our design team responded to educator needs.

Barriers to remote teaching and learning

Unsurprisingly, the first barrier that educators cited to remote learning (including but not limited to FUSE) was lack of access to technology. For example, of the 43 educators that we surveyed, 11 said that all of their students had access to the necessary online platforms for remote learning; 21 said that most (75-100%) had access; 6 said that many (25-75%) had access; 3 said that some (1-25%) had access, and one didn't know. Similarly, 10 said that all students had access to video-conferencing; 20 said that most (75-100%) had access; 6 said that many (25-75%) had access; 4 said that some (1-25%) had access, and one didn't know. When asked what kind of devices students were using to access online content from home, 16 said that students were using Chromebooks, one said they were using iPads, 3 said they were using laptop or desktop computers, 21 said they were using some combination of these devices and other smartphones or tablets, and one was unsure. Finally, in describing students' sharing of these devices, 26 educators said that students had their own devices (either issued by school or owned by student), while 26 said that some/all students had to share a device with others, and three were unsure.

These data show that access to necessary technology (a critical non-human actor for remote learning) was far from universal both within and across schools. This is to be expected, as many of our partner educators came from under-resourced schools serving populations that are majority low-income. However, for the most part, our education partners positioned this as a surmountable barrier and had identified solutions for addressing it. For example, many schools sent home laptops, iPads, or Chromebooks owned by the school (either one per student, one per family, or one only to each student/family who needed it). To provide WiFi to those students (and teachers) who needed it, some districts worked with local cable companies or sought donations from local businesses to provide WiFi hotspots for families in need. However, needs-based computer and WiFi distribution programs were dependent upon parents reaching out and requesting the needed technology, which didn't always happen, creating ongoing barriers to e-learning for a small number of students.

In addition to these general technology barriers, affecting all remote learning, in facilitating FUSE remotely, teachers and students faced an additional, more unique, technology barrier: access to specific software and physical tools and kit materials needed to do some of the challenges. As of March 2020, there were five FUSE challenges that could be completed entirely with open-source, web-based applications and therefore could be easily done at home. There were an additional five that involved online 3D design followed by 3D printing of the designed object. For these challenges, everything but 3D printing could also be easily done at home. There were two challenges that could be completed at home using cheap, everyday materials: *Spaghetti Structures* (which required spaghetti and marshmallows) and *Slow Your Roll* (which required paper or cardboard, tape, and a marble or other small ball), and there were two challenges that used software that was free but could only be downloaded on a desktop or laptop computer (not on an iPad or Chromebook). So these two challenges could be done at home, but only if students had the right type of device and the appropriate administrative access to download software (not always the case, particularly on school-issued devices). The other 17 FUSE challenges were designed to be done using kit-based materials (or a combination of digital tools and kit-based materials), which students did not have access to during spring remote learning. Therefore, they could not be completed remotely. So, while roughly half of FUSE challenges were available to students in some form while they worked remotely, the other half were not, and even those that were available were in some cases only available to some students (software challenges) or were only partially completable by all students (3D printing challenges). As a result, the primary way that educators said the FUSE team could help support them in implementing FUSE remotely was to design more challenges that could be done with the tools and materials students could access from home.

The second barrier to participation in both school broadly and FUSE specifically, described by both teachers and students, was the problem of competing home and school interests and responsibilities. Regarding competing interests, one student, 'Jackson', talked about feeling distracted by other activities at home and having a hard time focusing on schoolwork, saying, "It's tough to like stay focused on the tasks…like every time I try to like work on something, I get like off task, to like music or like video games or something. And that's, uh, it's been leading me to like, not do some of the work. So like, it's kind of hard for me to pay attention." He elaborated further, saying, "[I]t's just a cluster of tabs on my computer. And sometimes I don't know the question or the answer, or uh, a word or a question. So I have to like search it up and then I just have like 20 tabs open on like Google, trying to explain the one topic that I, I was trying to explain myself." Importantly, while Jackson described having difficulty focusing on schoolwork during remote learning (both in and out of FUSE), he said that in his free time, he was pursuing a wide range of learning activities related to his interest in a career as an astronomer or aerospace engineer, including watching National Geographic, Bill Nye the Science Guy, Iron Man, and other Marvel movies; playing video games, such as No Man's Sky and Space Engineers; coding in AI and Brainwaves; and solving a complex math equation for fun.

Home responsibilities also competed for students' time and attention. For example, we heard from educators that middle and high school students were being tasked with watching younger siblings while parents worked or were themselves working in essential jobs to help the family (in some cases because their parents had lost their jobs). For example, one high school teacher shared some of the students' stories she'd heard, in response to the question, "With all that is going on, what have you struggled with during this time?", saying,

> [M]ost of the answers are heartbreaking. Parents lost jobs, student still works an essential job. So they're working to pay the bills now and save up for that car they wanted, the other stuff. An aunt passed away, not COVID-related. Working all day, getting schoolwork done late at night. 'Parents still work, but I'm the teacher now and have to take care of my siblings and make sure they're learning and getting work done for them and bathe them. Then I get my schoolwork done when my parents get home.' 'My parents still work, but I'm an only child, so I'm home alone all day, until 7:00 PM at night, and I feel lonely.'

As a result, many students either didn't do schoolwork at all or were doing schoolwork and sending questions to teachers in the middle of the night, because that was the only time they were able to do it. For example, the same high school teacher said, "One girl messaged me. She got into FUSE and she was having a question. Well, she messaged my Google voice number at three in the morning."

While this problem was not unique to FUSE, neither was FUSE exempt from having to compete (and often losing out) to students' other interests and responsibilities at home. Our interview with Jackson shed some light on why FUSE may not have been as successful at holding students' interest and attention at home as our prior research suggests that it has been at school. He explained that during in-person FUSE, he enjoyed working with friends and preferred working on hands-on, kit-based challenges, such as those involving Arduino breadboards or building a solar car. At home, the collaboration piece was missing for him, as was access to these kit-based challenges. He described working solely on the computer as more distracting, saying "[I]t's easy to be distracted while building, but still be able to build and work on it. But on computers, I just get fully distracted and I take my mind off of the thing I'm working on."

Competing priorities in adapting instruction to a remote context

Teachers adapted to these two barriers to remote learning in different ways. How they adapted to them was decisively shaped by how they made sense of and navigated a series of competing priorities with regard to remote teaching and learning. First, in order to overcome the barrier of competing interests and responsibilities, educators had to negotiate a tension between two competing priorities: Is it better to foreground traditional subject matter content or foreground engagement? Some teachers and administrators believed that since students (and teachers) had limited time and attention to dedicate to remote learning, perhaps it was most important to prioritize covering core subjects, material that met standards, or things that might later be covered on standardized tests. For example, one teacher explained that even though standardized testing had been suspended during the pandemic shut-down, her administration's priority was still on math and reading – the things that would later be covered on standardized tests. In contrast, other teachers and administrators prioritized students' socio-emotional well-being and promoted activities that were fun and engaging, to motivate students to want to engage more in remote learning.

How educators balanced these competing priorities had implications for FUSE implementation. The schools that chose to foreground traditional subject matter coverage over engagement either didn't do FUSE or made it an optional extra, rather than an emphasized or required part of the remote learning curriculum. For example, an educator from one school that decided not to do FUSE remotely explained the reasoning behind that decision, saying, "[T]he challenge is trying to actually reach the students, for their normal…what is typically normal academics and trying to actually get over the hurdles of…reaching them with distance learning. So we've had so many challenges on that with that regard that unfortunately FUSE has actually taken a back seat." In contrast, those education partners who foregrounded engagement tended to include FUSE as part of remote learning. In some cases, the negotiation between these competing priorities was a negotiation between the FUSE teacher and their administration. For example, one teacher explained that although her administration's priority for remote learning was on math and reading, she decided to do FUSE anyway, because she wanted to make sure that her kids were "emotionally okay" and wanted to "give them fun things to do."

A second, related set of competing priorities that educators experienced in dealing with both the technology barrier and the competing interests and responsibilities barrier was a negotiation between prioritizing choice or prioritizing accountability. Because not everyone had access to technology or was interested/able to engage in remote learning, most educators decided to prioritize flexibility and choice and decrease accountability (both to increase engagement and address equity concerns). However, some educators had the opposite response, opting to increase accountability and decrease choice, to make up for having less contact with students and being unable to monitor their progress in the usual, more informal ways (e.g., walking around the classroom). For example, one teacher said that her administration had laid out three guiding principles for remote learning – "flexibility, grace, patience", which she had tried to incorporate into her remote teaching. However, she expressed frustration with colleagues who had failed to put these principles into practice by assigning as much or more work than they would in person, prioritizing accountability and resiliency, rather than flexibility and choice.

In FUSE, this meant that some educators retained or even expanded the choice aspect of FUSE (a core feature of FUSE in its typical implementation in schools). For example, one teacher talked about how his administration had encouraged expanding the number of choices available to students within FUSE and expanded the choice aspect of FUSE to other subjects during remote learning, saying, "[W]e have choice boards, which…we have to create by department for all the departments…and then the students are supposed to choose the activities that they're going to work on…or there might be options on how they're going to do it. With STEAM [FUSE]…we have nine choices on there [each week]." This meant that, in addition to regular FUSE challenges, the FUSE teachers also designed additional, related STEAM activities for students to choose from, organized around weekly themes (e.g., Star Wars projects for May the Fourth, Earth Day projects, and healthcare worker appreciation projects). In contrast, other FUSE facilitators eliminated choice by assigning one activity per week (either a FUSE challenge or a STEAM activity of their own design), in order to increase accountability.

Those facilitators that assigned weekly challenges tended to also layer in additional elements of accountability, such as requiring the completion of one challenge/activity per week or requiring written reflections after challenge completion. While some of our partner educators had implemented these sorts of accountability measures prior to the pandemic, most had not, and we spoke with specific partners who explicitly discussed newly implementing them during the pandemic, to increase accountability. This trend was interesting, because it existed in tension with the fact that, during remote learning, grades were largely eliminated or assigned as "pass-fail", a practice which was common in many FUSE classrooms previously but uncommon in schools broadly.

A third major decision that educators had to make in implementing remote instruction generally was how they were going to use available technology, particularly video-conferencing. When we surveyed our education partners on whether they were using video-conferencing during remote learning, eight said no, 20 said yes, it's optional, and 13 said yes, it's required. On one level, this decision hinged on which of the two barriers to participation in remote learning educators viewed as more problematic, interest/engagement or equitable access to technology and time to participate synchronously in instruction. If educators were more concerned with equity issues, they de-emphasized video-conferencing, but if they were more concerned with interest/engagement they incorporated more video-conferencing. On another level, this decision was shaped by a tension between a desire to enforce online safety and a desire to allow open collaboration or other forms of interaction. For example, one teacher explained why her administration had banned video-conferencing with students, saying,

> [W]e were instructed not to do live instruction for the legality of it, so liability of it, but also [it's] very difficult to pin point, because we have run the gamut, as we just discussed, of, socioeconomics, to pinpoint a child to a specific time to sit down in front of a computer. It seems all well and good that, yeah, well, they go to school from eight to three, just pick a time between eight and three, but we know that that's not the normal schedule right now for families.

> So we have been, we've been told we can do phone calls. We can do video calls without the video, just the audio. We can record ourselves instructing and post that, but no live instruction.

Other teachers did incorporate some synchronous video-conferencing into their remote instruction. However, almost universally, educators at our partner schools had decided that video-conference collaboration had to be monitored by an adult (i.e., students couldn't be on a video-conference call without an adult present). In some cases, a teacher also could not be alone on a call with a student. The reason cited for both of these decisions was a fear of someone doing or saying something inappropriate. This same reasoning also extended to asynchronous forms of collaboration. For example, many of our partner educators used tools like Google Classroom that would have allowed for peer to peer text chatting or commenting on work, but they specifically disabled these features, in order to avoid inappropriate comments and/or to not have to monitor for the (in)appropriateness of comments.

For an environment like FUSE, which typically relies heavily on peer collaboration in pairs or small groups, this proved problematic. Typically, during in-person FUSE, we see students going to peers or the FUSE website for help first, then, only as a last resort, going to teachers. Our interviews with teachers and students this Spring show what happened when peers were removed as accessible help resources in FUSE. For example, one of the students we interviewed, Kayla, from a class that didn't use any synchronous videoconferencing during FUSE, emphasized how much she missed the collaborative aspect of FUSE, saying "[During in-school FUSE] you would figure things out and collaborate. And that's one thing I definitely miss about FUSE and STEAM in the classroom, because [at home] you're like…collaboration, you're lacking that, you're totally self-taught. And it's just FUSE is there to help and guide you, but it's just a lot different from like a normal classroom."

She elaborated on the ways in which she thought FUSE did support her in working remotely, saying, "I really don't think there's much you could do to make it any better for FUSE at home…it's an online teacher that helps us tremendously, especially while we're at home and we don't have, you know, that teacher that we could access by crossing the room." In these words, we see two broader trends in our data reflected. First, in the absence of opportunities to collaborate and seek out help from peers, students were more likely to seek out help from teachers, but second, because teachers were also less easily accessible, students were largely forced to solve problems independently, relying mostly on resources on the FUSE website. One of the teachers we talked to reflected on this dilemma. When we asked her what the primary barrier was to her students doing FUSE at home, she said, "For some of them it's lack of access to the materials…for others, it's lack of access to me…You know, when one of my eighth graders, you know, had said to his mother, he says, you know, if we were just in school, I could just ask [teacher's name] and she could show me how to do it, and it would be okay." Other teachers elaborated on this theme, explaining that often, during remote learning, when students did reach out with questions via email, text, or direct message, by the time the teacher got around to responding, the student had either figured it out themselves and moved on or they'd gotten frustrated and given up.

Meanwhile, while technically, students could have independently collaborated with peers on FUSE, by hopping on a phone call, video call, or text chat, on their own, using an outside device or platform, we did not hear of any instances of students doing this, unless they were explicitly encouraged or required to do so by teachers. For example, one exception to this was when a teacher assigned a group project, called a "together apart challenge", where one student was expected to start the challenge, then pass it to another person to do the next part, etc. The only other examples of collaboration that we heard about were collaborations between siblings in the same house. As a result, collaboration was the number one thing that students and teachers reported as missing while implementing FUSE remotely and reported that they wanted to find ways to improve.

Design adaptations

In order to respond to the barriers and competing sets of priorities experienced by our partner educators and students, the FUSE design and implementation team focused their energy during Spring and Summer 2020 in three specific areas: new challenge development, the development of new tools and resources on the FUSE website, and virtual professional development workshops on remote teaching and learning.

In order to address lack of access to kit-based challenge materials, preserve the choice aspect of FUSE, and keep students engaged, the first thing that our design team worked on this spring was designing additional challenges that could be done at home. For the team, this meant focusing development on two types of challenges: (1) "DIY kit challenges" – hands on challenges using everyday household objects; and (2) digital only challenges – challenges that could be done from home using only free, online applications that are accessible across platforms (iPad, Chromebook, Mac, PC). The first DIY kit challenge that our team developed in Spring 2020 was, *Look No Hands*, which asked students to use household objects to create a Rube Goldberg machine. The second challenge, developed in Summer, was *Video Magic Tricks*, a videography and special effects challenge that uses a free, online application that is compatible across platforms. In Fall 2020, our team began redesigning two of our existing challenges that previously required software downloads, so that they use free online applications instead.

To support students and teachers in implementing FUSE remotely, our team has also added a number of new features to the FUSE website. First, to help facilitators support students remotely, our team created several, additional student-facing help videos for the FUSE website, including: "How to FUSE", "How do I choose a challenge?", and "Try Something New!" Second, we introduced a virtual whiteboard called "Studio Notes" – a space where facilitators could post announcements or pin important information for their students, just like they would do on a real whiteboard, in their physical classrooms. Third, to address the need for more and better remote collaboration, our team developed a new tool called "Help Finder". This tool was based on representations that teachers had previously created for their in-person FUSE studios, such as the "Boss Board" or "Star Board" (Ramey & Stevens, 2020a) and was designed to facilitate, in the digital space, some of the collaborative practices typically observed in a FUSE studio. For example, in a typical, in-person FUSE studio, because students work on different challenges in different orders, relative experts in different tools and challenges emerge (Stevens et al., 2016). Students then seek help from these relative experts when they have questions on those challenges. Students also frequently choose challenges based what other students in the room are doing and choose to collaborate with others based on shared interest in a particular challenge. "Help Finder" is designed to facilitate these practices in the digital space, by allowing students to see which of their classmates have previously completed or are currently working on different challenges, and who is actively available online (perhaps at 3:00 AM) to answer questions or work together in real time. However, this tool still has to be used in conjunction with other online collaboration tools such as discussion boards or video-conferencing, which brings us to our last area of development.

In order to share insights from our team and our community of FUSE facilitators on how to use new and existing tools to best adapt FUSE to remote learning, we developed a series of professional development resources and workshops. In Spring 2020, we sent out two memos highlighting new tools and suggesting practices educators might engage in to support students doing FUSE remotely. During summer 2020, we ran professional development workshops for new and returning FUSE facilitators. For returning facilitators, this took the form of a one-hour webinar, focused on adapting FUSE to a remote context. This included reminding facilitators of the core design features of FUSE (choice, engagement, collaboration) and providing simple recommendations for how to use internal (Help Finder, new challenges) and external tools (video-conferencing, Google Slides, Google Classroom, Padlets) to facilitate these features of FUSE remotely. For new facilitators, this same content was incorporated into a larger, two-day professional development workshop, conducted via video-conference.

Discussion

The findings presented here show how educators have adapted the FUSE learning environment to remote teaching and learning and highlight specific barriers and competing priorities that they faced in doing so. Specifically, we found that most of our partner educators continued offering FUSE remotely but, in doing so, faced barriers related to students' access to technology and competing interests and responsibilities at home (i.e., changes in the network of humans and nonhumans involved in teaching and learning). These changes had implications for student engagement and experiences. For example, Jackson reported being less engaged in FUSE, because he didn't have access to kit-based challenges, couldn't collaborate, and found working on the computer at home distracting. Similarly, Kayla reported missing the collaborative aspect of in-person FUSE but said that the FUSE website provided significant support when working remotely.

In addressing these barriers, educators had to make sense of and navigate three sets of competing priorities, including: (1) foregrounding required subject-matter versus foregrounding engagement; (2) prioritizing choice versus prioritizing accountability; and (3) promoting online safety versus promoting unrestricted, open collaboration. In some cases, teacher-facilitators themselves felt a commitment to both competing priorities. In other cases, these sets of competing priorities were being negotiated across organizational levels (e.g., between teachers and administrators). In both cases, how educators navigated these sets of competing priorities determined how they adapted FUSE (and other instruction) to remote learning. These adaptations, in turn, shaped how students experienced FUSE. For example, while students reported that the resources on the FUSE website were helpful in supporting their remote work, limits on free collaboration in the virtual space and lack of synchronous access to teachers and peers meant that students missed teacher and peer support.

Our findings also speak to the larger question of how/whether educators adopt and adapt educational innovations, particularly in times of crisis, and how educational designers might support them. For example, consistent with findings from prior research (e.g., Antonioli & Montresor, 2018; Ben Zur & Breznitz, 1981; Holl & Rama, 2016) we found that educators largely lacked the time, energy, and interest to engage in substantial redesigns of existing curricula or pedagogy, and in some cases, chose to shelve innovative, enrichment programming like FUSE entirely, in favor of core subjects. However, preliminary data collection during Fall 2020 has shown a potential shift in this pattern, with educators incorporating more innovations and innovative curricula into remote teaching and learning. It has also shown the impact of our team's design interventions, as we have seen significant uptake of the new challenges, tools, and instructional strategies created or suggested by our team and related increases in student engagement and collaboration.

As we continue collecting interview and survey data over the 2020-21 school year, the approach and findings provided here suggest questions for further investigation regarding the role of different human actors (e.g., teachers, administrators, students) and nonhuman actors (technology, building materials, ideas) in shaping how a program like FUSE (or teaching and learning broadly) is adapted to a remote context. For example, 'Which things are dependent on technology?', 'Which decisions are getting made at or negotiated between which organizational levels?' and 'How much agency do students or teachers have in decision-making around teaching and learning remotely (relative to in schools)?'

We would like to thank the FUSE design and implementation team and our partner educators and students for their hard work and dedication during this incredibly difficult time.

Students' Conceptualizations of the Role of Evidence in Modeling

Abstract: Modeling is a central scientific practice and is important for students to engage in and understand. Middle school students are able to identify scientifically appropriate criteria for evaluating model goodness, but struggle to prioritize a key criterion: fit with evidence. Although many studies have explored students' use of evidence, less is known about how students conceptualize the role of evidence in modeling, or reason about the importance of fit with evidence compared to other criteria. In this study we explored students' conceptualizations of the relationship between evidence and models by analyzing students' reasoning about criteria for good models. The results suggest that students conceptualize evidence in three ways: as a communication tool, as a way to determine accuracy, and as a way to determine accuracy mediated through inference. These findings can guide educators to facilitate classroom discussions that develop students' understanding about the epistemic nature of evidence.

Introduction

Modeling is a central scientific practice, and scientists across disciplines use models as a tool both for developing their understanding and for representing or explaining complex systems and phenomena in the world (e.g., Giere, 1988, 1999; Godfrey-Smith, 2006; Gouvea & Passmore, 2017; Schwarz et al., 2009). Scientists use epistemic criteria to guide them when constructing, evaluating, and revising scientific models (Hogan & Maglienti, 2001; Passmore & Svoboda, 2012). These epistemic criteria include that models are good when they *are explanatory*, *have an appropriate level of detail*, or *show a mechanism* (e.g., Pluta et al., 2011). Several educational guidelines and standards support giving students opportunities to engage with and reflect on scientific practices and their underlying epistemic commitments, such as criteria for evaluating epistemic products such as models (NGSS, 2013; NRC, 2012). In particular, these guidelines advocate for supporting students to develop their understanding of evidence, including the criterion that good models need to *fit with evidence*, in scientific knowledge building. For example, students need opportunities to reason about how data can be interpreted to draw conclusions, and how conclusions from larger a body of evidence can be used to determine the validity of models (Duncan et al., 2018). A number of researchers have echoed this support, noting the importance of helping students develop facility using evidence, and understanding importance of fit with evidence as a criterion for evaluating scientific knowledge and products (Duncan et al., 2018; McNeill & Berland, 2017).

In prior work we found that middle school students were able to identify a variety of scientifically appropriate criteria for good models even prior to an intervention (Av-Shalom et al., 2018; Pluta et al., 2011). However, students struggled to prioritize fit with evidence (Pluta et al., 2011). After an inquiry intervention over several months, students in Av-Shalom et al.'s (2018) study showed improvement both in using evidence and invoking fit with evidence as a criterion when evaluating competing models. However, many students still had difficulties using evidence productively. Although it is encouraging to see that students are able to develop facility using and discussing evidence, to further develop students' skills more research is needed to understand how students make sense of the role of evidence in knowledge building.

A number of studies have investigated how students develop scientific models and claims with evidence (e.g., Driver et al., 1996; Kelly & Takao, 2002; Passmore & Svoboda, 2012; Novak & Treagust, 2018). Other studies have explored how students reason about certain types of evidence (Lehrer & Schauble, 2017) or about evidence in certain contexts or used by different people, such as in science class or by scientists (McNeill, 2011). However, more research is needed to understand how students conceptualize the role of evidence in the development of scientific knowledge and the practice of using evidence to develop models. Further, little research has investigated whether students prioritize fit with evidence over other epistemic criteria for good models, or how students reason about the importance of fit with evidence. Scientists use evidence to guide them as they answer scientific questions and build scientific models (e.g., NGSS, 2013). To be able to participate in and understand knowledge building processes in science, students need to develop a sophisticated understanding of the role of evidence in model development and evaluation.

In this paper we explore whether younger students (fourth and fifth grade) are able to identify scientifically appropriate criteria for good models prior to an intervention, and how their individual lists compare to their shared consensus list. We then discuss an analysis of interviews of the same students after they participated in a short intervention, conducted as an after-school science club. In this analysis we explored how students reason about the criterion of fit with evidence and about the role of evidence in modeling. Thus, in this study we wanted to understand:

1. Which epistemic criteria do students in late elementary school (4-5th grade) generate prior to an intervention? Further, do students identify fit with evidence as a criterion and, if so, how do they prioritize it?
2. How do students conceptualize the role of evidence in scientific modeling after an intervention?
3. How do students reason about the relative importance of the criterion of fit with evidence compared with other criteria?

Theoretical framework

A central epistemic criterion in science is fit with evidence. That is, scientists use fit with evidence to guide their knowledge production and to determine the veracity of scientific knowledge products, such as models. Given its importance in science, several studies have investigated how students use or reason about scientific evidence when engaging with a scientific problem (e.g., Lehrer & Schauble, 2017; Manz, 2016) and whether they can differentiate evidence from hypotheses or claims (e.g., Ruffman et al., 1993; Sodian et al., 1991). In McNeill's (2011) study she found that fifth grade students were often able to identify that evidence is used by scientists to figure out what is true or find the answer to a question. However, in other contexts, such as when used in science class or in everyday life, students often conceptualized evidence as being for communicative purposes, such as convincing somebody or winning a debate, rather than for the purpose of answering a question or figuring something out.

Several studies have found that students of varying ages have difficulty connecting evidence with explanations (Driver et al., 1996; Sandoval & Millwood, 2006) and adjusting claims given new evidence (Novak & Treagust, 2018). Novak and Treagust (2018) suggested that some students do not change their claims in light of new evidence because they ignore the evidence, or because they do not conceptualize evidence as guiding the development of scientific knowledge. Other students do not synthesize discrete ideas from multiple pieces of evidence into a single claim, suggesting that they may not yet be proficient in looking across a body of evidence or understand the importance of doing so (Novak & Treagust, 2018). Although these are plausible reasons, further research is needed to understand precisely why students struggle to connect models with evidence and claims.

Further, despite agreement between researchers and standards documents about the importance of evidence, the concept of evidence remains underspecified in science education practice and research (Duncan et al., 2018; McNeill & Berland, 2017): In the research community and in standards documents, evidence is used at different times to mean empirical data, theories, personal experiences, data from simulations, science reports in news or other media, and others. Further, in traditional science classrooms students are often presented only with very simple evidence and do not have opportunities to engage with the complex nature of evidence, nor to discuss the epistemology of evidence and its role in scientific knowledge building. For example, traditional science classrooms often present evidence as strictly factual, rather than guiding students to understand that evidence is collected, constructed, and interpreted by people (McNeill & Berland, 2017), and that there may be multiple legitimate interpretations. Thus, in order to leverage and develop students' skills, it is necessary to identify students' epistemologies about evidence and evidence-theory relationships. This can also guide researchers and educators in clarifying the construct of evidence as it pertains to science education practice. Researchers and educators will then be able to improve methods to support students in forming a more robust understanding to ground their engagement with evidence.

To address these challenges, in this study we explored students' conceptualizations of evidence. First, we expanded on our prior research on students' metacognitive understanding of epistemic criteria (Av-Shalom et al., 2018; Pluta et al., 2011); our previous research focused on middle school students (seventh grade, ages 12-13), but in the current study our participants were younger students, in elementary school (fourth and fifth grades, ages 9-11). We explored whether students at this age were already able to identify fit with evidence as an important criterion for good models. Following this, we focused on two interrelated components of the criterion of fit with evidence: how students conceptualized the relationship between evidence and models, and how students prioritized fit with evidence in relation to other criteria that they identified for evaluating scientific models.

Method

Research context and participants

The participants in the study were students in upper elementary school (grades 4-5; ages approximately 9-11), who were participating in an after-school science club (n=20) at a charter school in northeastern United States. Based on the state report card, 21.3% of students in the school were Asian, 8.6% Black or African American, 7.2% Hispanic, 60.1% White, and 2.9% were of two or more races. Also, 12.9% of students had disabilities and 4.7% were considered economically disadvantaged. The school performance was above average, ranked in the top 2% of public schools in the state. The science club ran once a week for six weeks, for 1.5 hours each session.

During session 1 of the club, students engaged in a task to introduce scientific models. In this study we chose to focus on explanatory models which provide a causal account of the mechanism underlying a phenomenon, in line with others in the field (e.g., Windschitl et al., 2008). During the task, students saw six sets of two to three models, each about the same topic, and were asked which model was better. These sets were designed to highlight different epistemic criteria. One of the five sets that the students saw is shown in Figure 1. Students were asked, "Which model best explains how plants get their food and energy to grow?" The model on the left includes a clear mechanism. In contrast, the model on the right has pictures, which may be attractive to students, but explains less about the mechanism, and includes extraneous and confusing elements (e.g., the person letting out air). This set highlights the criterion of *showing a mechanism* and calls into question the importance of *having pictures or visuals*. Students looked at these models in pairs, and later discussed them with the whole group. Students were not told a "correct" answer, nor were they told which criteria to attend to. After looking at the model, students developed individual lists of criteria for what makes a good model, and later had a whole-group discussion to develop a "club list" of criteria.

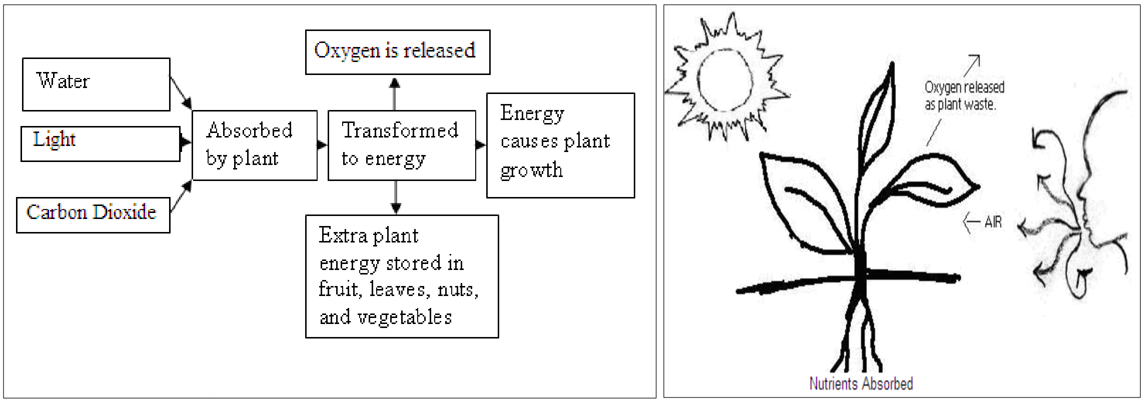

Figure 1. Set of models that students were shown.

In sessions 2-5 of the club, students were presented with a "mystery" to solve, in the form of a story. In this story a child added several fish to a fish tank, but after some time the fish died. In order to figure out what happened, students explored a variety of resources, including NetLogo agent-based computer simulations (Wilensky, 1999) and empirical research, primarily in the form of text-based reports (Rinehart et al., 2016). These resources were developed by the research team and designed to teach students about the broader biological context of carrying capacity. The range of resources was designed to align with the diversity of resources used by scientists when developing their understanding of phenomena. Students used these resources to construct, evaluate, and revise scientific models in small groups (3-4 students) and as a whole club.

In session 5, students revised their club criteria for good models and discussed the differences between the two types of resources that they engaged with. In sessions 5 and 6, small groups (2-3 students) were interviewed for 15-20 minute. We chose to interview students in small groups rather than individually so that they would feel more comfortable to share their thinking, and so that they could have discussions together and build and elaborate on each other's ideas. The interviews were open ended, guided by prompts, about topics pertaining to club activities including the relationship between fit with evidence and other criteria discussed in the club in determining model quality.

Data analysis

The data sources included videos of all the club sessions, screen captures of sessions in which students were using computers, and student artifacts. In this study, we focused on students' written work, club criteria list, and videos of their interviews. To identify the epistemic criteria that students generated prior to an intervention we analyzed students' personal criteria lists, developed on the first day. On this day, 17 students attended, and we collected all of their lists and categorized the criteria that they included. The categories were adapted from coding schemes used by Av-Shalom et al. (2018) and Pluta et al. (2011) to categorize students' model-quality criteria. The findings were supported by comparing with the club criteria list that students agreed upon following a discussion.

We also did an exploratory analysis of students' interviews to investigate students' conceptualizations of the relationship of evidence to models, particularly contrasting with two other criteria: accuracy and understandability. We focused on interviews in which students were asked at least one of the following five questions: 1) Is it possible for a good model to have accurate information but not fit the evidence?, 2) Is it possible for a good model to fit the evidence but not have accurate information? (asked as a follow-up to question 1), 3) How do you determine accuracy? 4) What's more important: being understandable or fitting the evidence?, or 5) Students were given a scenario in which a town experienced a problem, and two people developed models to explain it, one model being clear and easy to understand, but not fitting the evidence, and the other fitting the evidence but being more complex and harder to understand. They were then asked which of the two models would be better (asked as a follow-up to question 4).

In their criteria lists and group discussions, students used a number of terms which seemed somewhat conflated with evidence, such as "accuracy," "true facts," and "accurate information." In designing our research questions, we intentionally used similar language with the assumption that there was some shared understanding and norms of usage of these terms between students. We also wanted to see whether and how students would elaborate on and compare the terms when answering the questions.

Students in five interview groups were asked at least one of the prior questions. One group was not included in the present analysis because their interview was cut off prior to the students being able to say enough to establish a clear conceptualization from any of the students. The four remaining groups consisted of nine students (three pairs and one trio). All students were interviewed during the last session (week 6) of the club.

Results and discussion

Criteria lists

At the beginning of the science club, students individually developed lists of criteria for good models. Table 1 shows the criteria listed by three or more students. The frequencies show that many students were able to identify scientifically appropriate criteria, such as good models being explanatory and fitting with evidence. The students were allowed to talk with their peers while developing their criteria lists, and criteria lists of students sharing a table tended to have high overlap. Thus, the frequencies likely do not fully reflect what would be seen if students had developed the lists individually, which may explain why the frequencies of certain criteria such as *evidence* are present more frequently than we have found in previous work, when students did not collaborate (e.g., Pluta et al., 2011).

Table 1: Criteria raised by three or more students on their individual criteria lists.

Criterion	Number of students
Labels	14
Facts (including real facts, true facts, accurate facts, and true information)	12
Details	10
Explanations / Explains	9
Evidence (includes one instance of "proof")	9
Picture/Diagram	8

Criterion	Number of students
Sequence	8
Reasons	6
Clarity	5
On topic	4
Convincing	3
Understandable	3

After developing their individual lists, students had a whole-group discussion in which they agreed on a shared list for the club. Their list included six ranked criteria (1 being most important, 2 second-most, etc.) and six unranked, supplementary criteria (Table 2). It is notable that despite being on more than half of the students' personal criteria lists evidence was only added as a supplementary criterion in their shared club list, not as one of the six "most important" criteria. Also, on their shared list students prioritized "true facts" over "evidence." These findings suggest that although students may be familiar with the need for evidence, they may not yet understand that "facts" or claims need to be supported by evidence. That is, that fit with evidence is the primary way to determine "truth" or accuracy.

Table 2: Students' shared criteria list

Ranking	Ranked Criteria
1	Based on true facts
2	On topic (stay focused on the thing we want to explain)
3	Includes an explanation (explains)

Supplementary Criteria
Is clear and organized
Is coherent (makes sense)
Includes examples

4	Description & details	Evidence that supports the model
5	Has labels	Convinces the person that is reviewing it (is convincing)
6	Shows sequence/steps	Includes pictures

Conceptualizations of evidence

The students' individual and club criteria lists suggested that they may not fully understand fit with evidence as a key criterion to determine the validity of models. To shed light on how students conceptualized the role of evidence in modeling, we analyzed students' interviews. In this process, three conceptualizations of evidence emerged, evidence as (1) a communication tool, (2) a factual determiner of accuracy, and (3) a determiner of accuracy *as mediated by inferences*. Each will be discussed in turn.

Evidence as a communication tool

In their interviews, several students' responses suggested that they considered evidence to be a tool for supporting their ideas after the ideas had been established, usually for persuading or clarifying for others. In this view, a model is developed by identifying accurate claims and then, if necessary, choosing supporting evidence. As Kyle (all student names are pseudonyms) said, "if you don't have accurate facts there's no need for evidence at all. And if you have accurate facts but no evidence that's still a little enough to persuade the person." Later in the interview he added, "evidence is something that supports your facts." In this case, Kyle seems to be using "facts" to refer to his claims. According to his conceptualization, a person first needs to identify accurate or true claims before deciding whether supporting evidence is necessary or available.

When discussing what people should do if they found evidence that contradicted their model, Arun said, "You can change your claim or change the evidence." In general, students with this conceptualization of evidence said that depending on the situation a person could choose to change your model or to change or discard the contradictory evidence. Their choice could be based on which was easier to do, or else based on your own ideas or on your review of the model (without using evidence). When discussing whether to keep or discard contradictory evidence, Tegan elaborated on how a person would know which pieces of evidence were important, saying, "Because if you have true and accurate facts that are clear you could find the correct evidence. First, you could find evidence that supports your theory or hypothesis. Then you learn the true and accurate facts. Then you see which evidence supports which, and if you don't need any evidence, you don't need it."

Students who conceptualized evidence as a communication tool all seemed to understand that evidence is important in scientific practice; for example, that evidence is useful to "prove" an idea. Further, these students preferred models which were complex and difficult to understand but fit the evidence versus models which were simpler but did not fit the evidence. However, they shared a misconception about the connection between evidence and models. Canonically, evidence is a key arbiter of scientific models and claims. Scientists construct, evaluate, and revise models and claims based on evidence, and it is the model, not the evidence, which must be changed in response to incongruencies with the evidence. Students with this conceptualization of evidence expressed that it was more or equally appropriate to fit the evidence to the model than to fit the model to the evidence.

Initially, some students with this conceptualization of evidence appeared to develop a more canonical view of evidence with only slight guidance. In the excerpt in Table 3, the interviewer probed Arun about his idea that he would have made an accurate model prior to choosing evidence, and he changed his mind, saying that evidence was in fact necessary. Several times after this, Arun's statements such as, "if the evidence is wrong then the whole model will be wrong," suggested that he now understood that evidence was the arbiter of accuracy. However, later in the interview he was asked whether a model needed to fit with all of the evidence or just some. He argued for all, saying "… it [the model] needs to support all the evidence 'cause your evidence needs to prove the whole claim. You can change your claim or change the evidence." This excerpt shows that he still did not have a clear understanding that evidence supports models, instead saying that the model needed to support the evidence. Furthermore, he returned to his original position that when faced with contradicting evidence a person can choose whether to change the claim or the evidence. Like other students who conceptualized evidence as a communication tool, Arun's understanding seemed to be that when developing models a person must determine accurate claims or "true facts" first, and that identifying supporting evidence can be identified afterwards.

Table 3: A student changes his mind.

Interviewer	What I'm hearing you [Arun] say is that it's important for it to be accurate but you're already assuming that it [the model] fits the evidence and the evidence is correct.
Arun	Yeah, evidence should be correct. No, you like, first it has to be accurate before you choose your evidence.
Interviewer	But what do you mean *choose* your evidence?
Arun	Before you have the evidence, you need your claim or whatever you're saying to be correct.

Interviewer	So how are you going to know if it's correct if you haven't looked at evidence?
Arun	Oh yeah, you need evidence, yeah… so yeah you need evidence. Yeah, I changed what I was saying.
Interviewer	So you're saying evidence is more important?
Arun	Evidence is more important.
James	Yeah because the evidence um, like, wouldn't always be right, so you need to get the right evidence for the information to be accurate.
Arun	I agree with James.

Evidence as a determiner of accuracy

Students who had this conceptualization stated that evidence helps a person know or prove what is true or whether a model or claim is accurate. During Michael and Adam's interview, Michael noted that it was impossible for a good model to fit the evidence but not have accurate information, saying, "If you have evidence and not true information then there's no point in the evidence because it's not true anyway." The students were then asked whether it was possible for a good model to have accurate information but not fit the evidence (Table 4).

Table 4: Student discussion about the connection between fit with evidence and accuracy

Interviewer	So is it possible for a good model to have *accurate* information but not fit the evidence.
Adam	*No*
Michael	Well, it can be okay, but it can't be very good.
Adam	Well, let's say the model has no evidence, but it's true. It's still *true*, except-- I agree with Michael, it's at least better than the non-true evidence.
Michael	Yeah
Interviewer	Now, how would you know if it's true?
Michael	Because um… you wouldn't. You wouldn't know unless there's any references or anything like that…

In this excerpt, the students concluded that although models can be true even without supporting evidence, it will be impossible to tell without additional information. Note that Adam's response in this excerpt, "let's say the model has no evidence," suggests that he interpreted "not fit with evidence" to mean *not be supported by evidence* rather than *be contradicted by evidence*; that is, these students likely understood that a model would not be "true" if there was contradictory evidence. This is supported by their other statements. For example, the two later agreed that the purpose of having evidence is, as Michael said, "to make sure if it's [the model is] true."

Overall, students with this conceptualization argued that evidence is necessary to determine accuracy. Some students further elaborated by saying that an absence of evidence means that it is impossible to determine accuracy. Students were also able to articulate that contradictory evidence is usually an indication of inaccuracy and said that when confronted with contradictory evidence people need to change their claims or models.

Students with this conceptualization also reasoned about the relevance of evidence to models when presenting the model to others. Michael and Adam also stated that in some cases it may not be necessary for models to fit all available evidence (Table 5). He then added that a person needs to tailor the amount of evidence presented to the background knowledge and interest of the audience.

Students with this conceptualization reasoned about the relevance of evidence to models when presenting the model to others. Michael and Adam also stated that in some cases it may not be necessary for models to fit all available evidence (Table 5). When they were then asked about a person should do in response to contradictory evidence, Adam responded, "Well, you can *fix* it." He and Michael then added that even though supporting evidence is important, a person needs to tailor the amount of evidence presented to the background knowledge and interest of the audience. They then discussed that if there is too much information "sometimes your brain just can't hold it," and adding that in those situations "you probably know it, and there's no point reading" and that "then you're missing all the information." In conclusion, Adam noted that when presenting a model, you should only include "the evidence that is most important and most needing to know [sic]."

Table 5: Students discussing whether a model needs to fit all of the evidence or only some of it.

Michael	It's better to make all of it, but you don't have to, 'cause you might know some of the stuff, but I mean the author sometimes doesn't put *all* the evidence because sometimes you just know, it's obvious to everyone.
Adam	We don't *need* all the evidence, but it would be more helpful if someone just got on this topic to have all the evidence out for them, and to know that this test actually…
Michael	Yeah, so you know for sure that everything you're reading is true and you're learning something.

Evidence as the determiner of accuracy as mediated by inferences

Students with this conceptualization of evidence are consistent with the prior group in that they understand that using evidence is necessary to determine accuracy, and prioritize fit with evidence over other criteria. Ajay argued that fitting with evidence was more important than being understandable "because then if you put the evidence but it's not a good claim then it doesn't even matter because you don't have the right stuff." Cooper also said that she would "rather read something that's very complex and that doesn't make sense to me the first time and read it a few times over than read something that's perfectly understandable to me but has no right information."

However, students with this conceptualization also expressed that people needed to use evidence appropriately and skillfully in order to reach accurate conclusions. In one interview, Emily gave an example explaining how it is possible for a good model to fit the evidence but not have accurate information, "So, for example, you have evidence that Raj's fish was in a clean tank, alright? But your information is that Raj's clean tank stayed clean, because it started in a clean tank. So, you have the evidence that Raj's fish started out in a clean tank, but your conclusion from it is not accurate." Raj was the main character of the mystery that students were trying to resolve, and Emily's example highlighted that students could draw incorrect inferences from the evidence that was available. In this view, their model might fit with the evidence, but still be inaccurate. Cooper later added that "you can have a reason and have it explain the evidence but also have that reasoning be wrong."

In another interview, Ajay argued that a model could have accurate information but not fit real evidence, "Yes, because it can prove a different topic, maybe not that topic but it can be a different topic." He added that in some cases a model could fit the evidence but not have accurate information if it included a "fake claim."

Conclusion and contribution

This research shows that, prior to an intervention, students as young as fourth and fifth grade can generate productive criteria for good models. Moreover, both their individual lists and their shared consensus list included a variety of scientifically appropriate criteria, such as good models needing explanations and a sequence. However, the findings suggested that some students may not yet have understood that evidence determines accuracy, which may explain why students across studies have struggled to prioritize using fit with evidence to evaluate and revise knowledge products, such as scientific models.

In the analysis of student interviews after the intervention, we found that students had three different conceptualizations of evidence. Two of them, evidence as a communication tool and evidence as the determiner of accuracy, align with McNeill's (2011) findings that in some contexts students said that the purpose of evidence was to convince or in other ways communicate ideas to others, whereas in other contexts they said that evidence was the way to determine truth. However, in our study we found that some students were also beginning to develop a more epistemically sophisticated conceptualization of evidence, that its meaning is inferred by people. However, these students still did not demonstrate an understanding that there can be multiple legitimate interpretations.

Importantly, the findings also indicate that students as young as 9 to 11 years old can articulate their conceptualizations about the role of evidence in evaluating and revising models, and some may already understand that fit with evidence is used to determine accuracy. However, students' responses in this context suggested that they may need scaffolding to reach more sophisticated understandings of evidence as constructed and open to multiple interpretations. This study was conducted in a high performing school (see section on participants), so the results may not reflect how all children at this age range perform on these tasks. Even so, the results further our understanding of the different ways in which students may interpret the role of evidence in science.

The findings also suggest that short prompts to reflect on evidence may help students who view the role of evidence to be for communication purposes move towards a more sophisticated understanding of evidence as way to determine truth, but that more scaffolding may be necessary to sustain that understanding. Further research is needed to identify the best strategies for promoting epistemic growth in this area.

Students in this study included several criteria on their criteria lists and in their whole-group discussions which may seem conflated with evidence, such as "facts," "true facts," and "accurate information." We intentionally used similar terms in the interviews with the hope that students would elaborate on and compare the terms when answering the questions. Thus, they could express their ideas in ways that helped us understand how they understood them to be related. Students' usage did bring up some important insights, such as that students seemed to conceptualize evidence as disconnected from "true and accurate facts." Such conceptualizations may in turn affect students' ability to value evidence and evaluate models based on evidentiary fit.

Understanding students' conceptualizations may guide researchers in clarifying the construct of evidence as it pertains to student understanding in the classroom. Educators may also be able to leverage the range conceptualizations of evidence seen in their classrooms in order to promote dialogue between students about the epistemic nature of evidence that will help students develop and refine their understanding.

Mathematical Physical Research: Mathematical agency in the practices of professional dancers

Lauren Vogelstein, Vanderbilt University, lauren.e.vogelstein@vanderbilt.edu

Abstract: Research in embodied mathematics has shown that the body is fundamental to understanding mathematics, yet how to support learners in seeing and leveraging these connections remains an open question. This paper explores how bodies, a vital resource for intuitive sensemaking, can be leveraged to support agentic forms of mathematics learning that foregrounds the interpersonal relationships learners cultivate. To do this I studied professional dancers who used their embodied practices to explore and choreograph mathematical ideas. I traced these dancers' practice, *physical research,* from the dance studio to their participation in a double stimulation experiment in which they were asked to reenact mathematically salient choreography from a large-scale ensemble performance. This paper takes up recent methodological calls in the learning sciences to use the relational histories of learners in their embodied practices of disciplinary learning.

Although mathematics is commonly understood as a disembodied, Platonic discipline, scholars in mathematics education have argued for the importance of recovering the body for mathematics learning (Hall & Nemirovsky, 2012; Stevens, 2012). Lakoff and Núñez (2000) traced the discipline of mathematics backwards to embodied semantic primitives. By linking the form of the human body to the mathematics that we have today, Lakoff & Núñez argued that embodied resources for sensemaking were fundamental to the historical development of mathematics, even if not to contemporary mathematics teaching or learning. An entrenched history in math education has positioned the body as a container, with the sole purpose of transporting a thinking brain, which means that inviting learners to ground their mathematical sensemaking in their bodies is not always an invitation that is accepted, taken up, or trusted. While the body is an omnipresent resource for learners in all contexts, it is commonly dismissed or erased in formal learning environments, as learners routinely do not see their everyday embodied activities as mathematically relevant (Moschkovich, 2002; Nasir et al., 2008). Thus, it is insufficient to invite learners to use their bodies for mathematical sensemaking without better understanding culturally and historically laden practices that foreground the body as the primary site for sensemaking. As more research explores the multimodal and embodied ways learners can make sense of disciplinary ideas (Hall & Nemirovsky, 2012; Ma, 2017; Marin et al, 2020), a question remains: how can we design math learning activities in which learners have reason to trust their bodies as resources? In this paper I propose that looking to the practice of professional dancers may provide answers, as their sensemaking centers on embodied forms of collective noticing as ever present and crucial to exploring how they can express and make sense of mathematical entities.

Motivation

A group of four 8th grade girls were participating in an exploratory mathematics activity: I asked them to reenact a moment from the opening ceremony of the 2016 Rio Olympics in which performers folded large flexible silver squares into triangles. The girls folded their own similar square prop into a triangle, but disagreed about what kind of a triangle they had folded. They placed their large triangle on the ground and engaged in an enthusiastic debate as to whether it was a right triangle (with a 90 degree angle) or an isosceles triangle (in which two edges have equal length). Ava started the debate standing fixed at one edge of their triangle, "IN MATH [...] you're not going to turn the math book and say it's a right triangle, you're gonna say that's an isosceles." Octavia supported Ava's argument for team isosceles, "when they give it to you they don't put the 90 up there ((pointed to the angle on the floor Tracy argued was 90 degrees)) [...] They don't put the 90 up there. THEY DO NOT DO THAT in books."

Here, Ava and Octavia (all names used in this paper are pseudonyms) used school-based mathematical epistemologies cultivated from paper-scale geometry to reason about their large, walking-scale triangle, deferring to a fixed understanding of what "they" do "in math." This was perfectly reasonable. The implicit norms in mathematics textbooks correlate orientation with geometric properties by deferring authority to the invisible authors of these books, allowing for quick recognition. These sensemaking resources employed "in math," however, limited the girls' engagement with the mathematical properties being discussed, as they accepted a static, decontextualized understanding of mathematical rules, even for a mathematical object they had made by moving together at walking scale (Vogelstein, Brady, & Hall, 2019). The moment these girls labeled their activity as "math," they turned away from their embodied sensemaking resources both within themselves and each other.

The ubiquity of our bodies, as inseparable from our existence, makes them a fundamental resource for how we make sense of the world around us. Thus, if we want to ground mathematics learning with these powerful resources, we must leverage the body as a powerful source of reasoning which is not a trivial task. In this paper I examine a contrasting case to the one described above to show how professional dancers' in the company, Novel Tectonics, engaged in this same activity in a way that linked their mathematical reasoning to their embodied practice called "physical research," building mathematical discoveries from agentic and embodied forms of reasoning. By engaging in their practice of physical research, these dancers took up mathematical reasoning in expansive ways. The 8th grade girls wanted to do this, but did not have a toolkit to support this kind of reasoning and thus were far more constrained. The practice of physical research has important structures to support collective mathematical sensemaking that links embodied noticings to ensemble mathematical learning in a way that foregrounds participants' individual and collective creativity and agency.

In this paper I analyze the response of professional dancers (in conversation with 8th grade students' response) to an embodied mathematical activity I created to intentionally support learners' recruitment of everyday, embodied reasoning. This activity was presented in a double stimulation interview (Engeström, 2007) in which participants were presented with novel tools (large prop and video recording from Rio) to accomplish a task (reenact folding choreography from the 2016 Rio Olympic Opening Ceremony), designed to provoke observably creative solutions for study (Vogelstein et al., 2019). Building mathematical learning from intuitive sensemaking means that learners see these forms of reasoning as valuable and part of their everyday lives and not stuck in the isolated context of mathematics (Hall & Jurow, 2015; Nasir et al., 2008). In contrast to the episode of 8th grade girls' reasoning about their mathematical choreography, professional dancers framed their engagement in this context as a practice of inquiry, flexibly leveraging embodied sensemaking resources to explore what was expressively possible within the people-plus-prop system. Instead of reaching a solution quickly (inverting the relationship between speed and intelligence), these dancers slowly created new possibilities and ideas together. The dancers referred to this practice as *physical research*, recruiting how they participate in a dance environment to this hybrid movement and mathematics context. In physical research participants explore their unknown expressive potential as an ensemble through an iterative process of creating and responding to collective, full-body movement. This foregrounds artistic agency and collective persistent inquiry (Lerman, 2014; Sengupta-Irving & Agarwal, 2017). The dancers' engagement in mathematical physical research in the interview points to new possibilities for expansive mathematics learning through their embodied mathematical sensemaking. To that end I explore how the practices of professional dancers can broaden our conceptualizations of epistemic mathematical practices by asking the following research questions:

1. How did dancers engage in processes of physical research in their professional context and what forms of participation did this support?
2. How did dancers engage in physical research to support mathematics reasoning in the context of the Rio interview and what forms of participation did this support?

I address these questions by using an ethnographic study (Lave, 2011) to trace the cultural practice of physical research from the dance studio to the double stimulation interview (Engeström, 2007). Use of physical research in the interview setting shows how dancers leveraged this practice for mathematics learning. I operationalize learning as a socially distributed process of changes to participation in a community of practice (Lave & Wenger, 2011) and directly take up recent methodological calls in the learning sciences to contextualize analyses of disciplinary learning in the history of participants' relations as mediated by embodied practices (Gutéirrez & Rogoff, 2003; Vossoughi et al., 2020). Dancers' use of mathematical physical research offers a new way to think about the designs for mathematics teaching and learning that place everyday resources of the body on par with symbolic or graphical resources in conventional approaches to mathematics education (Gerofsky, 2010).

Theoretical framework

Ensemble learning

Ensemble learning (Ma & Hall, 2018) references activities that are done with others that cannot be learned alone. These activities are necessarily a collective endeavor in which participants recognize the need to learn as a group, such as a high school marching band preparing for a competition or professional dancers engaging in an exploratory choreographic process where the group explores what they can express collectively (Lerman, 2014). Analytically, this necessitates a shift in the unit of analysis from the individual to the ensemble. This does not mean that individuals and their contributions are erased; rather, this shift contextualizes individual contributions in how they inform the group's work together and highlights the coordinated efforts of distributed learning (Danish et al., 2020; Ma, 2017).

Ensemble mathematical activity can expand *what* is possible to learn in mathematics contexts by changing the scale and modality of geometric objects, thus re-scaling the body's relationship to geometric figures and changing the modality of engagement. In traditional paper-scale geometry, learners maintain a bird's eye view and an authoritarian relationship to manipulating small objects. The representational infrastructure of mathematics changes when the scale and materiality of geometric objects change (e.g. 7' x 7' shiny silver Mylar square) so that manipulating geometric objects now requires the participation of a group. This disrupts canonical embodied routines and creates new possibilities for modal engagements, understanding, and participation in mathematics learning (Hall, et al., 2014; Ma, 2016; Vogelstein et al., 2017 & 2019). For example, in the Rio interview, dancers choreographed a way to find the midpoint of one edge of the prop by having two people hold adjacent corners with one hand to create a taut edge for their other hand to slide along. When the two hands met they were in the middle of the edge and had found the midpoint. This is an excellent example of how modalities of engagement shifted from using a ruler to first measure the entire length and then divide it in two, to two hands sliding towards each other. This led to a conceptualization of midpoint that highlighted the relationship between the defining points, enacting the same travel time from end points to midpoint. This relational understanding of a mathematical concept was built from the coordination of moving bodies and perspectives.

Embodied mathematics

Ensemble activity foregrounds the importance and necessity of *doing* things together since these activities cannot be done by someone on their own, which highlights the body as a central to learning. How the body is used in learning processes (embodied learning), however, has been theorized differently by many scholars. Stevens (2012) outlined two theoretical perspectives characterizing the majority of embodied mathematics literature: conceptualist and interactionist. He argued that the conceptualist stance positions the body as revealing cognition in the brain (Alibali & Nathan, 2012; Lakoff & Núñez, 2000) and the interactionist position commits to seeing cognition in interaction (Goodwin, 2000; Nemirovsky et al., 2012). I take an interactionist perspective which aligns with Kirsh's (2010) notion of physical thinking, in which studying a choreographer revealed how physically enacting movements affords opportunities for observations and actions that could not be accessed through simulation or without direct participation. Notably, becoming mathematical entities through exploratory dance research can bring relations into existence in meaningful ways (Kremling et al., 2018).

When geometric figures are re-scaled and necessarily manipulated by an ensemble, noticings while moving become consequential for learning as learners gain an intrinsic perspective of the object they constitute together. For example, when the dancers slid their hands towards each other to find their midpoint, they began to notice how this action leveraged the midpoint as an anchor for the folding sequence that followed. Coordinating both intrinsic and extrinsic perspectives adds to the depth of mathematics learning in these environments by emphasizing how components coordinated together constitute complex mathematical objects. Embodiment constituted *in* the movement of ensembles shows how being immersed inside and outside of mathematical phenomena supports the coordination of multiple perspectives which leads to new forms of engagement and sensemaking that positions learners as agentic and actionable mathematics thinkers..

Intercorporeality and relationality

Expanding possibilities in mathematics education through studying ensemble learning from an interactionist and embodied perspective highlights how individuals' movements are understood in relation to the whole group composition. Participants gain a view of mathematical structures from their intrinsic perspective, while also engaging in mathematical sensemaking with others as they are forced to coordinate distributed perspectives and participation to create objects together. Thus, how groups learn to reason as a group through the development of new relations is foregrounded in these learning environments (Sengupta-Irving & Agarwal, 2017).

Leading work in the learning sciences has called for research that values new forms of relationality as outcomes of learning (DiGiacomo & Kris D. Gutiérrez, 2016; Vossoughi et al., 2020), expanding what it means to take changes in participation as evidence of learning (Lave & Wenger, 1991). As an intimately connected practice enacted with an ensemble, physical research supports the development of *intercorporeality* (Meyer et al., 2017), or a sense of withness. Hahn and Jordan (2017) argued that evidence of intercorporeality is a change in participants' identities from I's to we. Embodied anticipations begin to stabilize as reciprocal responsibility develops, which also supports empathy and *intercorporeal trust*. Empathy and trust are important sensibilities to cultivate in learning environments, and are commonly absent from mathematics contexts (Cooper, 2010).

Tracing the practice of physical research over the years has shown deep reciprocal relations between these dancers, foregrounding intercorporeal trust as a fundamental aspect of their practice. Thus, when these dancers entered into the Rio interview they were able to draw upon well-established relations of trust in each other to both explain what the Rio dancers did and to create new performance elements. Analysis of the dancers' developed sense of withness, and a substantial repertoire of language and body practices for engaging with this mathematical task importantly expands understandings of what mathematics learning can look like and result in.

Methods

This paper traces the practice of physical research through ethnography and a double stimulation interview. The 90-minute interview was designed as a Vygotskian double stimulation experiment (Engeström, 2007), which allows researchers to observe participants' inventions in response to novel situations such as choreographing geometric transformations with a large Mylar square. Initial analysis of professional dancers engaging in this interview prompted two years of ongoing ethnographic observations to better understand the practice of physical research in the context of the dance studio and how the dancers leveraged it in the interview.

Participants and research context

The primary participants consisted of 10 professional dancers and the artistic director, Clarke, of a contemporary dance company, Novel Tectonics, located in a mid-sized city in the American Southeast. Almost all of the dancers moved from all over the country to work in the artistic "research lab" Clarke created where dancers explored how they could collectively embody new ideas. While foregrounding the exploratory nature of dance is not unique to Novel Tectonics, it is noteworthy that these dancers moved to a new city for a job that was not enough to make ends meet. Clarke described this artistic community as follows: "We are Black, White, Latinx. We are gay, straight, bisexual, Christian, Jewish, believers in science, and atheists." The dancers' diversity was reflected in physical research by leveraging bold movement proposals that reflected their unique perspectives. Dancers have expressed that leveraging their artistic agency and allowing them to express possibilities they could not explore on their own drew them to this community (Vogelstein, 2020).

Data sources and analysis

Ethnographic data

Novel Tectonics rehearsed 3 hours a day, 5 days a week from September to May. During the 2017-2018 & 2018-2019 seasons, I observed 1-2 rehearsals a week for a total of 50 observed rehearsals. Data collected during rehearsals included field notes that describe observations of how these dancers engaged in cycles of physical research as well as video recordings of their work. Field notes were collected as a means to capture events and impressions from being present as an observer, supplementing the inherently limited view of the camera lens, while video recordings captured the fast moving bodies of the dancers to allow for micro-ethnographic Interaction Analysis (IA) of how multimodal aspects of gaze, gesture, and coordinated movements were used in interaction (Hall & Stevens, 2015).

Double stimulation interview data

The Rio interview was designed as a double stimulation experiment (Engeström, 2007) in which participants were presented with a primary stimuli (the Rio Olympic reenactment task) to make their uptake of a secondary stimuli, representational supports or tools (large square Mylar prop and video recording from Rio), observable. As a whole, the interview consisted (1) of showing a group of 4 people a performance from the 2016 Rio Olympic opening ceremony, (2) asking them to reenact parts of the performance using a similar prop, (3) having them discuss the relevance of mathematics in this activity, and (4) allowing participants to choreograph their own performance with the prop. 4 cameras recorded the interview (2 cameras on adjacent walls, 1 on the ceiling, and 1 on the table), approximating the different angles used in the viewed recording of the Rio performance. Analysis of the dancers' participation in this interview shows how they leveraged consequential embodied sensemaking resources by engaging in physical research.

Findings

How these dancers engaged in physical research professionally

This analysis demonstrates how engaging in the practice of physical research allowed the dances to collectively engage in expansive, agentic mathematical sensemaking in which, unlike the 8th grade girls, mathematical authority resided in their own seemingly simple observations. Analyses of the first year of ethnographic data illuminated the basic structure of physical research in practice (Vogelstein, 2020) across multiple contexts. In the rehearsal studio, cycles of physical research were enacted through making and responding to physical proposals between the choreographer and dancers to develop "movement vocabularies" and then "sculpt" them through proposals to change what had been established. Framing any movement enacted as a proposal meant that movements were always thought of as something that could be responded to, ideas that others could and should build off of. Choreographic proposals for sculpting existing movements were generally verbal prompts to alter what the dancers had created (e.g. enact these moments but in a diagonal formation) from an extrinsic perspective, to which the dancers used their bodies to respond to these new arrangements by making new proposals and responding to each other physically from an intrinsic perspective until something had formed, a referenceable movement vocabulary, that the choreographer could continue to sculpt (Figure 1).

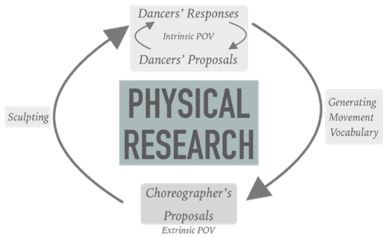

Figure 1. Model of physical research

This model of physical research helps illuminate how these dancers participated in this practice, proposing ideas with their bodies that they responded to until something had solidified that could be observed and then sculpted. As they engaged in this practice year-in and year-out, their ability to work together as an ensemble also developed as proposals and responses blended into trusting movements together:

> I feel like it happens physically because […] there is also like a trust that like the body like has some understanding of what's happening just by the person in the room being in the room. You know, I feel like there's something that is exchanged in that, that chain of sharing that is more than verbal. […] Maybe it's the way that Maddie makes a proposal and I then, you know, follow up. […] It's still improvisational but there's still a sense of knowing. You know, like if I end up behind Maddie and my arms are in front of her then she knows that if she wanted to she could like thrust all of her weight back and I could fall safely. […] And it's through the doing and the redoing I think too (Darius, Interview March, 2019).

Committed to the notion that people's physical presence affects what is possible, Darius described physical research as a process developed by moving in response to and with others. He linked this to the relationships with his colleagues, where trust supported them to exchange ideas and move in new ways together without words. He emphasized, "doing and redoing," in which long-term trajectories of participation support the development of intercorporeal trust as an innate part of physical research. In the next section I use this ethnographically-grounded model of physical research to analyze these dancers' collective mathematical sensemaking in the Rio interview to show how physical research can support agentic forms of mathematical reasoning that can also foster new forms of relationality through trust as a valued outcome of learning.

How these dancers engaged mathematics in physical research in the interview

In this episode, four dancers from Novel Tectonics (Cathy, Darius, Faith, & Maddie), participated in an experimental hybrid movement and mathematics activity in which they were working on reenacting choreography from the opening ceremony of the 2016 Rio Olympics that involved a quartet folding a large silver flexible square sheet of plastic into a triangle. Over the course of a 20-minute process of physical research, the dancers iteratively refined their understanding of the referent choreography by exploring together what was visible in the video record and what was possible to create with the prop together.

By engaging in this mathematical activity through their collective practice of physical research, the dancers continuously explored possibilities with the people-plus-prop system (quartet and square prop), making new discoveries until they were "satisfied" and stopped. Framing their activity as physical research meant that the dancers continued to redefine how they could fold the prop into the desired shape. Their engagement focused on exploring possibilities rather than perfecting the execution of a set sequence of movements, remaining open to opportunities for changes through new proposals. In the following analysis I outline the dancers' physical research trajectory as it led them to discover three different embodied understandings of the concept of midpoint and how the resources involved in cycles of physical research supported this engagement.

Physical research of a triangle: Three different ensemble coordinations used to find a midpoint

Noticings from the video record became crucial to the ensemble's engagement in physical research as they coordinated their extrinsic perspective of the performance from re-watching the video with their intrinsic perspective as a part of a group manipulating a similar prop. These intuitive sensemaking resources, comparing observable configurations, were easily taken up in their inquiry. For example, early on the group identified that the camera angle used to broadcast the performance captured observable triangles with one 90-degree angle and three sides of different lengths (a right scalene triangle). The dancers proceeded to fold the square prop on the floor to prove that creating the desired triangle was possible. On the floor, the first proposed movement was a grab at the midpoint of one edge, to which another dancer responded by using this as a fulcrum to fold her corner up and over across the midline of the object, this was the first way they found this midpoint together.

In addition to coordinating observations from the video with their own roles in the choreography, the dancers also responded to how they manipulated the prop together, engaging with it as a fifth member of the group that needed to be supported. Once they had folded a right scalene triangle on the floor, they transitioned to a standing up configuration, sculpting their movement vocabulary. Once they stood up, the dancers quickly discovered that they needed to actively pull corners to tighten edges in order to make folds along the same lines as they had on the floor, reconfiguring the supports the floor had passively provided. However, now that active force was needed at the corners of the square, nobody could reach to grab a midpoint. Cathy and Faith creatively slid their hands along the taut edge between them using the symmetry of their movements and the length of their wingspans to find the midpoint between them. This second movement vocabulary for establishing a midpoint was found by responding to the new configurations and movement vocabulary they continuously developed.

After choreographing a triangle-folding pattern standing up, utilizing points that created tension to fold across straight edges, the dancers had solidified a new movement vocabulary but some were still not satisfied. Faith and Maddie made a proposal to sculpt this vocabulary by incorporating a visual formation the Rio performers' "hit" in the video that they had not yet created. Faith's proposal to sculpt, "Yeah let's do the dumpling airbag," (Figure 2A) came from an extrinsic perspective on the choreography, positioning Faith as the choreographer in this moment. The "dumpling-airbag" referred to a formation where all four performers started with their prop extended as a square and all walked to the center together, puffing the prop into a dumpling-like shape below their waists. Observing and naming this formation allowed the movement to be referenced and reenacted as a group. Maddie led the group in enacting this formation, coordinating their movements with a verbal cue, "So, dumpling," (Figure 2B). Creating the dumpling formation was the group's response to Faith's sculpting proposal and once formed, Cathy's new intrinsic perspective led to a new way to find the midpoint, "oh and then find our edge here," (Figure 2C & D) as opposed to pulling it tight as they had before. The dumpling folded the prop without a need to stretch edges taut and in fact folded each edge in half so that the midpoints between corners now puffed out between members, making it easy to grab as the edges collapsed in half. Confirming the utility of this formation, Faith followed up by announcing to the group, "this is how they do it," (Figure 2E). This comment solidified the generation of a new movement vocabulary, setting the group up for another process of sculpting as they continued in their cycles of physical research.

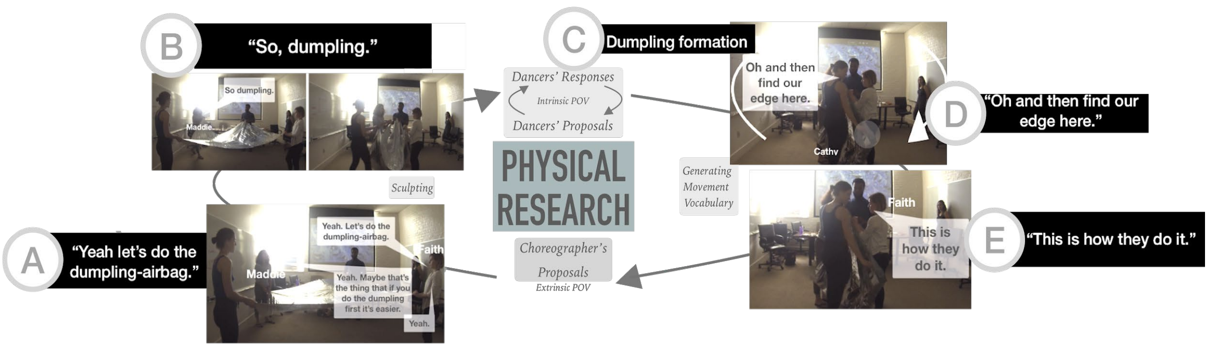

Figure 2. Mapping the dancers' mathematical discovery that midpoints can emerge through symmetric movements onto the preliminary analytic model of physical research

This example of the development of finding the midpoint of an edge, distributed amongst the dancers, shows how engaging in cycles of physical research structured participation so as to make small, intuitive noticings (e.g. all of the Rio performers gathered together at one point) about the aesthetics of movements consequential and productive for inquiry. One small proposal became important as it was amplified by seeding responses from other members distributed in the group as individual wonderings became whole group enactments (from I's to we's). The relations of trust enabled deeper understandings of what can be done and at the same time the relational structure of the mathematical object (the multiple ways the prop could be folded across a midpoint). These forms of reasoning are typically not available when this sort of mathematics is engaged with at paper-scale under circumstances in which individuals manipulate entire geometric figures on their own, foregrounding the resultant state and not relations and pathways in movement. It is also important to note that proposals to sculpt in this process of physical research supported a process of mathematical engagement in which discoveries were being made, even 17 minutes into a 20-minute inquiry process, constantly fueling new ideas, formations, and understandings from the dancers.

This analysis demonstrates how these dancers' engagement in physical research in the Rio interview supported the use of everyday sensemaking resources for agentic mathematical reasoning. Simple noticings of measurement, orientation, and configurations led to the development of complex embodiments of three different ways midpoints could be found and used as anchors for symmetric transformations. Additionally, this analysis shows how physical research structured the use of these sensemaking practices to support new relations between learners because as the dancers engaged in this activity their fluency in responding to each others' movement proposals increased through the development of intercorporeal relationality and trust.

Discussion and significance

To concretize the importance of this paper, I return to the opening example. Although Ava and Octavia's intuition when folding the prop into a triangle was to recruit disembodied forms of reasoning used, "in math," their eagerness to engage in an extended debate about the properties of a triangle and resultant conclusion. Eventually Tracy persuaded Ava by showing that in the creation of the triangle one of the corners came from a square and since it was not altered in the process of folding, it must have remained 90 degrees. Tracy's insistence and Ava's change in reasoning points to students' willingness to engage their intuitive, embodied sensemaking skills, although not always right away. Imagine what kind of mathematical participation these girls could have engaged in if they had exercised their agentic forms of embodied sensemaking from the beginning as physical research supported the dancers' mathematical reasoning or had trusted each other and built off of each others' proposals, as the triangle in question was actually both right *and* isosceles.

This paper contributes to work in mathematics education to better understand practices (such as physical research) that support embodied, everyday sensemaking resources learners already possess as relevant to mathematics inquiry. The observations the dancers made and acted on utilized basic embodied sensemaking resources (e.g. mirroring slow movements, noticing visible differences in formations) that the 8th graders could have enacted, yet it was engaging in the practice of physical research, a practice that had cultivated their ability to work as a collective, that enabled these dancers to engage in such deep and generative mathematical inquiry.

Studying these dancers' engagement in physical research, both in the dance studio and in the interview, shows the development of a responsive collective agency through the making and responding to proposals as an ensemble. This enactment of agency shifted the relations between the dancers, supporting collective and embodied forms of mathematical inquiry and imagining. By illuminating the structures of activity that supported physical research over time, this analysis both challenges normative conceptions of mathematical learning as mediated primarily with pencil-and-paper and illuminates possibilities to guide current and future designs of innovative and inclusive embodied mathematics learning environments. Questions about how to design to support these collective practices so that learners see their everyday, embodied sensemaking resources as mathematically relevant remain. Drawing from these initial findings, I have begun the next phases of this work, co-designing and co-analyzing mathematics activities with the dancers of Novel Tectonics, using their practice of physical research to structure forms of participation for students that are promising in initial analyses.

A New Mixed-methods Study of Learning-at-disturbance in Experienced Designers

Xiao Ge, Stanford University, xiaog@stanford.edu
Larry Leifer, Stanford University, leifer@stanford.edu
Linlin Shui, Communication University of China, cucsll@cuc.edu.cn

Abstract: We propose and validate a new mixed-methods approach that enables micro-level analysis of knowledge construction as well as high-level understanding of learning dynamics across person, space and time. The learners being examined here are experienced designers who exhibit adaptive expertise of reconstructing knowledge and adjusting behaviors in situation. To study this learning process of designers, first, we draw on theories of disturbance-based learning and identify high-arousal moments, or high-learning potentials, by capitalizing on unobtrusive emotional arousal measures of vocal pitch and electrodermal activity. Next, designers' learning at disturbance is characterized and understood through contextualization and triangulation with video observation and retrospective self-report using distributed views of learning. Together, our work shows how physiological measures such as voice could be integrated into the study of situated knowledge construction in the wild, and how the current mixed-methods approach offer new and more comprehensive ways of seeing and understanding knowledge in action.

keywords: knowledge-in-action, emotion, distributed cognition, multimodal learning analytics

Coming from the field of engineering design, our research is concerned with understanding the learning process in experienced designers' social practices. The focus on experienced designers and the stance of situated learning at disturbance is a confluence of multiple forces.

First, at the practical end, we want to unpack the expertise shown by adaptive expert designers, as compared to routine experts. Adaptive experts (Schön, 1983; Schwarz, Bransford & Sears, 2005) are able to reflect in action, adjust assumptions and modify behaviors during the process of product design in order to create new and meaningful product outcomes for peculiar problems at hand. A real-world example is elegantly described by Schön (1983). In a project of treating children malnutrition in rural Colombia in the 1960s, an unusual engineer Dean H. Wilson unlearned his convictions of system engineering through trial and error, and in turn, created successful educational interventions by grasping opportunities that lied in the intelligence of the local community. The pedagogical question of how to enable our engineering students and novice designers, to build up such adaptive ability has incubated the current research. Second, at the theoretical end, we are influenced by the interconnected streams of thoughts that, in Dewey's words, "thinking starts with felt difficulty" (Dewey, 1910). Our work is built upon this notion that surprise, confusion and discomfort have pivotal effects on learners' performance (Kapur & Bielaczyc, 2012) and knowledge development (Kegan, 1983; Bamberger, 2014; D'Mello, et al., 2014). For participants of social communities in our changing world, disturbance is ubiquitous, instead of rare, psychological phenomena (Berlyne, 1960; Moscovici, 1984).

As a result, we have come to see engineers and designers as dynamic learners who are often disturbed in their work, regardless of their expertise level and social-interaction context. In making this conscious choice of research perspective, we are aware that the teacher-student, parent-child, and master-apprentice paradigms are the basic building blocks of most educational research and have greatly driven the advance of learning sciences. On the other hand, change, the process of developing new beliefs and behaviors, is a process that would also occur for experienced professionals at work. In Schön's account, Dean H. Wilson's learning at work happened when he was a professor and expert engineer.

We join the emerging efforts of multimodal learning analytics (Blikstein & Worsley, 2016) and integrate technological tools with qualitative research to study the scarcely investigated learning process of experienced designers in the wild. Our work is a synergy and reflection of knowledge-construction-in-situ research as well as a methodological probing of how to study the interrelation of emotion and learning in the future.

Theoretical stance grounded in distributed views of learning

The views that situate learning in social and physical engagement have a long history in learning sciences since Piaget time. A leap of its development was seen in the 1980s and early 1990s (Bamberger & Schön, 1983; Brown, Collins & Duguid, 1989; Lave & Wenger, 1991; Pea, 1993). Despite different takes, the distributed views unanimously challenge the traditional view that knowledge is "a property of the minds of individuals" (Pea, 1993). We highlight a few influential theories below.

Knowledge-in-action is a concept initiated by Bamberger and Schön (1983), defined as "the current state of a person's mental constructions". The concept captures "the sense of movement and instability associated with, even necessary to, learning and change". According to Bamberger (2014) and Schön (1983), knowledge is mobile as a result of constantly interacting with the changing context instead of being stable, abstract and codified, the latter of which are often characteristic of other sociocultural views of knowing, such as cognitive schemas (Crocker, et al., 1984) and social representations (Moscovici, 1984). While knowledge-in-action stresses the continuous mobility of knowledge, as the learner interacts with materials at hand and the social context, distributed intelligence emphasizes the role of materials (e.g., technological tools that support learning) in terms of distributing and empowering intelligence, which is traditionally regarded as "a property of the minds of individuals" (Pea, 1993). This view is echoed in Papert's constructionism, which places significance on the role of different media in children's knowledge (re)construction (Ackermann, 2001). Others (Hutchins, 1995; Suchman, 1987; Lahlou, 2018) have demonstrated how workers' actions, which reflect their knowledge and expertise, are augmented with, controlled by and channeled through physical and social realities.

A designer's knowledge lives and grows through his/her mental, social and physical mediations, and in doing a design task, the designer engages in moment-by-moment construction of knowledge as he/she moves across time and space. This distributed view is contrasted with the traditional view in which to design is to enact a codified body of knowledge and skills. In addition, we take the stance there is not "a single, coherent and non-contradictory account of what happened", and that "real action is often ambiguous and may have multiple determinations" (Lahlou, 2018). However, references to the specific situation and designers' subjective experiences would lead to more complete interpretation and meaningful analysis (Xue & Desmet, 2019).

A new mixed-methods approach

Empirical approaches to study learning at disturbance range (e.g., experimental design in Kapur & Bielaczyc, 2012, inductive analysis in Bamberger, 2014). In works that adopt a situated view of knowledge, however, ecological validity has non-negotiable priority (Bamberger & Schön, 1983; Shaw, et al., 1997; Rahman & Barley, 2017; Parekh & Gee, 2019; Kulikowich & Young, 2001). The situated nature of knowledge favors approaches where real-world phenomena are largely preserved. Where intermediate self-reports are collected to gain access to participants' subjective experiences, ecological validity is compromised, and thus ecological momentary assessment has remained a challenge (Ram, et al., 2017).

Recent years have seen an emergence of new, non-obtrusive technological solutions and analytics (Blikstein & Worsley, 2016; Andrade, et al., 2016; Di Mitri, et al., 2018; Eteläpelto, et al., 2018) to enhance the ethnographic and phenomenological study of learning. Physiological measures, primarily electrodermal activity (EDA), are increasingly used for approximating students' emotional arousal in various learning contexts (Pijeira-Diaz, et al., 2018; Villanueva, et al., 2018). EDA refers to the variation of the electrical conductance of the skin in response to sweat secretion, which is produced by the sympathetic nervous system. Our skin becomes a better conductor of electricity when we receive external or internal stimuli that are physiologically arousing (Boucsein, 2012). And emotional arousal has long been regarded as an indicator for curiosity (Berlyne, 1960) and active participation (Pijeira-Diaz, et al., 2018). In contrast to EDA, Vocal pitch as a proxy for emotional arousal (Mauss & Robinson, 2009) has not found its way into learning sciences research. Vocal pitch is considered in literature as "less controllable and more leaky channels" of high emotional arousals that are not revealed by verbal content or facial expressions associated with the message (Zukerman & Driver, 1985; Dietrich, et al., 2019). The advantage of voice and sweat gland is that they make unobtrusive ecological assessment feasible, but they should also be used with caution. Unlike controlled-lab studies, their instrumentations in the wild would induce a lot of real-world noises which may make speech data difficult to clean up and electrodermal responses hard to interpret. In addition, the mapping between the basic physiological processes of emotion and experiences of emotion (i.e., what is felt) is still poorly understood (Barrett, et al., 2007). Subjective perspective-based video analysis, when triangulated with retrospective self-report, is a powerful qualitative measure (Lahlou, 2011) of experience and behavior, and could complement the bodily measures for validity-driven analysis.

The current research has been conceived to take advantage of aforementioned instrumentations. Our research question is a methodological one: *How to capture, characterize and understand the knowledge-(re)construction process of experienced designers at disturbance*? Considering our goal is to study learning through high-learning-potential moments of disturbances, emotional arousal measures of EDA and vocal pitch make it possible to identify high-arousal moments amongst large amounts of time-series data. To deal with the limitations of physiological measures, multiangle video data and retrospective self-reports are collected for interpreting the objective measures as well as to match our theoretical position.

The study of learning-at-disturbance in experienced designers

Participants and a half-day design task in the wild

Experienced designers were recruited based on accomplishments. They all started as engineers and went through rigorous human-centered design programs (from 1970s to 2019) from an engineering department at a U.S. university. The designers were randomly paired to work on a task in a naturalistic setting for three hours. None of them collaborated before. With a previously established measure (Atman, et al., 2010), we assessed their confidence, frequency of engagement in design activities, as well as how supportive their work environment is towards different types of design activities. The designers had on average 14 years of design work experience. Despite large variance of experience (sd: 15.28 years), they were on average highly confident (avg: 86.31 out of 100 with ad: 4.78), receive positive work-context support. We will focus on designer Diver (anonymous label) for qualitative analysis, Diver regarded himself as a design innovator, product designer, consultant, educator, researcher as well as magician. He was frequently engaged in the early front-end of product design, and these years only occasionally worked on the later stages of product realization. Diver had 40 years of design experience.

An ill-defined design problem was introduced. Given a set of videos and written materials, the participants were asked to create solutions to radically improve the dining experiences of families with small children. Video materials contain pre-collected data of eating scenarios from several families. To realize "in the field" experience, we crafted a temporary design studio situated at a place with easy access to children's facility, kitchen and residences of families with small children. The designers were physically unconstrained from the design studio. Two hours into the study, two families with their children came in for user testing. We suggested the users not make compliments only, but provide honest, critical and helpful feedback to the designers. By the end of the three hours, each team delivered a pitch as if to their client with some prototypes in hand.

Data collection and analysis

We used multiple observational channels to account for uncontrolled variables in the wild. Video cameras were mounted at the four corners of the studio. Each designer wore a miniature eye-level video camera, AXON Flex 2, to capture how situations are lived from the perspective of the participant (Lahlou, 2011) and keep track of design activity wherever the participant is, and it also provides audio data for speech acoustics analysis. Each participant also wore an Empatica E4 wristband on the dominant hand. The device acquires time-series data of EDA, movement, skin temperature, heart rate variability. Only EDA is used in the current study. Within a week after the study, participants shared subject experiences in a 2-hour one-on-one interview. Large prints of snapshots of the participants' own views, artifacts produced during the project, video clips of their subjective view, and other tools were used when appropriate to facilitate the unfolding of internal experiences.

Designers' engagement level is approximated by vocal pitch and skin conductance response (SCR) frequency, interpreted through triangulation. Audio data for each participant is extracted, manually cleaned up for speaker diarization and partitioned into utterances with ELAN software and analyzed with PRAAT software. Laughing, whistling and other sounds are separated from vocal speech. Creaky voices are identified with the Covarep program in Matlab and cleared from the dataset. To understand intraindividual change, each designers' utterances are segmented by design phase and social situation to calculate average and standard deviations of each phase and changes across phases. To allow for between-subject comparison, the baseline was acquired by rescaling vocal pitch to standard deviations above and below each designer's average vocal pitch (Detrich, et al., 2014). Utterances that are 1.5 standard deviations or more than the local average (i.e., z-score) are regarded as pointers to pronounced episodes of "felt difficulties", and thus high-learning potentials. These deviates are analyzed qualitatively through triangulation with EDA, self-report and video analysis. EDA retrieved from Empatica E4 was processed with Continuous Decomposition Analysis (CDA) as implemented in Ledalab program with Matlab. SCR is exported using a minimum amplitude criterion, which is a threshold that the rise in skin conductance value must reach or surpass to qualify as SCR. Since the current study took place in an uncontrolled environment, a score of 0.05 mS is used (Boucsein, 2012). We use SCR frequency to categorize the data into different levels. 1–3 peaks/min (ppm) is marked low (Dawson, et al., 2017), values higher than 20 ppm are interpreted as high arousal (Boucsein, 2012), while anything in between is medium. Signals less than 1 ppm are discarded for the purpose of data cleanup. Each designer's SCR frequency is also segmented by design phase and social situation. Lastly, retrospective self-reports are transcribed to provide a window into the subjective experiences of designers to support the data analysis.

Results

With the proposed measures, how to capture, characterize and understand the knowledge-construction process of experienced designers? We highlight case examples from designer Diver and show some micro-level analysis of "felt difficulties" which trigger designers' learning in action. Additionally, the mixed-methods approach allows comparative analysis of learning dynamics across person and time.

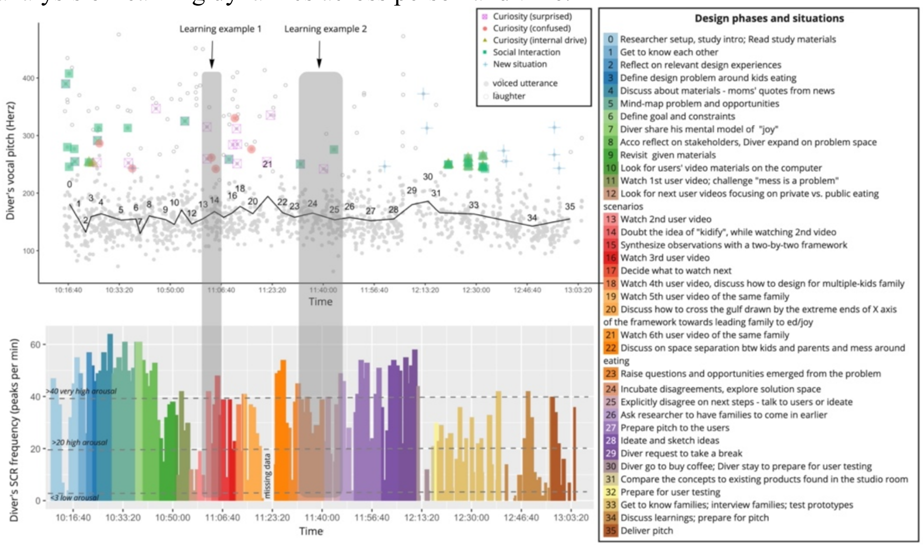

Figure 1. Designer Diver's engagement map; Top-left: Average vocal pitch over time (error bars not shown for simplicity) and types of high-pitch utterances; Bottom-left: SCR frequency, where arousal levels are based on standards (Boucsein, 2012; Dawson et al., 2017). The identification of high-learning-potential episodes (as indicated by colored shapes in top-left graph) is based on 1.5 z-score rule, and subsequently qualitatively coded through triangulation with SCR, retrospective self-report and video analysis. Grey bars highlight case examples.

Zoom-in: Characterizing and sensemaking knowledge reconstruction at disturbance

Learning example 1

Consider designer Diver's 2-minute experience here as he responds to a video material about a child interacting with food and utensils (Figure 2). Within the short time, Diver is channeled to speak in a distinctively high voice (1.5 z-score) a few times. In the quotes below, Diver's high vocal pitches are marked in *italic*.

After silently watching the video for a while, Diver turns to his partner Acco to offer his observation that adult products are scaled down for kids in softer materials, "*but it isn't clear*" (z-score: 1.89), he pauses, and does not finish the sentence before continuing, "we've seen these modifications in adult world of plates and utensils. So within the culture we are trying to kidify it enough that (unfinished)... It isn't clear it's helping the kids. And I think the parents go, this looks like it is for kids". He continues with a related observation from past experiences that some adult bottle designs are actually influenced by baby products and that "it literally went the other way around!" As the video plays along, he turns his attention back and forth between the TV screen and his partner. "*But I'm realizing it's a baby bottle!"* (z-score: 1.53), he excitedly points to the screen (as shown in Figure 2), "*But that…",* Diver quickly brings his hand back to hold his chin, and then stretches out to gesture, contradicting his earlier comment: "*and it works for her! It works perfectly. She had no problem with that*." (z-score: 1.66). While Acco acknowledges Diver's observation, Diver keeps watching the video, holding a fist by his chin, asking in a deeper and lower voice: "So are we looking at this the wrong way, that we wanted to have", he briefly pauses and turns to Acco, taking a lighter voice, "kids become adults versus learn from the kids and modify our adult world (with laughter)? That might not be hard to sell!"

Let us go through the thin slice again with our theoretical and analytical tools. A designer's knowledge lives and grows through their mental, social and physical mediations. And here, designer Diver curiously *saw* "kidification" as channeled by the video of child interaction with utensils. Diver's design knowledge around children's products is manifested in his ability to see kidification; In comparison, two less experienced designers in the study found this specific video material uninteresting. Moreover, instead of simply acknowledging kidification, Diver questioned it, and spent time on it, making it a rather intriguing issue. In addition to high voices, his body language suggests excitement, and his verbal expressions suggest confusion ("*but it isn't clear*") and curiosity (repetitive and contradictory statements). As he navigated the video, Diver broke down his assumption again and again, to further his understanding about kidification, from "*It isn't clear it's helping the kids*" to "*...it works for her! It works perfectly. She had no problem with that*" to questioning "are we looking at this the wrong way". The disturbance and elicited curiosity are also evident from the perspective of SCR frequency, where a steep rise occurs in the local proximity of the video-watching activity (Figure 1, bottom-left).

Example 1 not only shows the "mobile continuity" (Bamberger & Schön, 1983) of situated knowledge which is distributed in the physical (TV), mental (Diver's embodied expertise) and social (cultural practices associated with the child's dining) spaces, it is also a high-learning episode. Diver is grabbed by the visually colorful and soft utensils, curiously stuck on why designers should assume baby products are scaled downs of adult products. This question drives Diver, as a seasoned children's product designer, to unlearn the default assumption and reconstruct his knowledge in the space. It is notable that kidification might not be an entirely new concept to Diver. He may have developed this concept of kidification in his previous experiences. However, this alternative view is not made obvious and questionable until this disturbing moment as he engages with the video material, which allows Diver to adjust and expand his situated knowledge.

Figure 2. Designer Diver's subjective view (left) and a third-person camera view (right) of a high-learning moment for Diver, located at phase 14 in Figure 1. Left: Diver extends his left arm and points at the TV, saying "*But I'm realizing it's a baby bottle!".* Right: Acco (standing) observing user behaviors as Diver (sitting) talks.

Learning example 2

At a later point of time, Diver has a tense disagreement with Acco. After the user-behavior observations, Diver indicates a few times of his interest to talk to actual users. As Acco does not respond, Diver makes it an explicit request. But instead of supporting Diver's suggestion as Acco always does until this point, Acco proposes to design some sacrificial concepts first. Hearing that, a high-pitch voice leaks from Diver before Acco finishes his sentence. "*Hmm! um-hum!*" (z-score: 1.68). Diver is verbally positive, but his vocal pitch suggests surprise and discomfort. As an experienced designer, Diver is able to regulate his emotions and make conscious balance between maintaining teamwork and making the right pathway. He opens up to go with Acco's thinking process to ideate. After a few minutes of exploring the solution space, Diver is channeled back to think of talking to users, because one of their concepts is hinged on the question "when do kids transition from baby food [to family food]?" "That", Diver points to the TV, "looks like my plate, only it's not working!... And we literally had to separate ourselves from the kids because it doesn't work…Ah, I, I would love to ask about when you eat together, when you don't". In response, Acco insists on spending the limited time on coming up with some concepts and preparing for user-testing. Diver attempts to persuade Acco again — "We've thrown some ideas out around this stuff, and I'd love to see — are we even close to be on track", and he adds, "and our hypothesis is that they (parents and kids) are struggling eating together. I just, I want to validate that". But Acco also persists in his thinking. "*Okay"* (z-score: 2.14), responds Diver in an abnormally high voice.

As Diver reflected in the retrospective interview, he regarded the division with Acco as "the high point of perplexity". In Diver's view, the project ended in "anticlimax" partly because of that, even though they receive positive and encouraging feedback from the users during the user-testing phase. Diver was deeply convinced, based on his experience, that it is not wise to go too deep in concept generation without validating their underlying assumptions with users first. Intriguingly, Diver started navigating this "felt difficulty" with a positive attitude and open mind. During this process, there is no doubt that Diver was guided to shape understanding about the design project at hand, as new questions surfaced (e.g., when do kids transition from baby food to family food?). By cooperating on ideation, Diver built a new mental container that would accommodate product ideas while not stretching his own convictions too much. But that only led to building up tension in the conflict. At the moment when Acco expressed strong interest to work on concepts, Diver realized they had different conceptions of "concept" and "ideation" — while for Diver they already had some high-level ideas, to Acco these were not concrete concepts ready to be tested with users. As shown in the analysis, Diver's knowledge about Acco and how to work with Acco was being reconstructed moment by moment as well.

This experience also had a pivotal effect on Diver's subsequent performance. He was less curious about the task and less engaged behaviorally as well. Diver laughed much less (Figure 1, top-left) and showed fewer learning behaviors as indicated by the high-pitch criteria. Shifting lens to EDA, Diver's arousal does not make obvious sense as in example 1, since phase 24 and 25 are actually lower than the local proximity, despite the high baseline. This could be better understood through contextualization. In Diver's reflection, he described design progress as "going along where your energy is" and emphasized how important it is to "keep the energy up". For

Diver, the splitting point with Acco was a deflation of energy he gained from earlier activities. This is observable in his physical activation as well. Diver changed from the active posture of standing up and working by the whiteboard at phase 22 and 23 back to sitting down, as he tried to resolve the conflict. In comparison to example 1 in which Diver's high-pitch utterances suggest stimulation, excitement and curiosity, the high-pitch utterances of example 2 are briefer in length and suggest undesirable tensions.

The two examples here are complicated and pronounced ones, whereas in some other cases, the situated experience is rather brief. For instance, earlier in the process, hearing Acco's joke about their shared design training, Diver jokes as well: "*Okay, checked! Extra credit! We are done, we are out of here!*" (z-score: 1.83) It is clearly a team bonding interaction, where Diver is positively surprised and channeled to build his knowledge about his unfamiliar partner and how to work with him.

It is worth noting that not all high-pitch utterances suggest disturbance-based learning. Some of them are not elicited by disturbing stimuli but are due to uncertainty and curiosity to learn. For instance, in the user-testing phase, Diver asks one parent: "*Do you guys ever eat together at that table or do you eat separately*?" (z-score: 1.67). According to Diver's retrospective self-report, the answer to this question was very critical to validating his assumption behind the product idea. There are also exceptional arousal rises due to entering or expecting new situations, for instance, Diver raises his voice to say "*Okay!*", suggesting moving on to the next design phase. Fluctuation of pitch as associated with situation change has less to do with the kind of disturbance in our theoretical framing and can be distinguished by triangulation with qualitative analysis.

Zoom-out: Learning dynamics across time, between people

Designers' arousal level, as measured by EDA and vocal pitch, has notable changes across design phases and social situations. For instance, as shown in Figure 3, Designer Diver is situated in a much more highly aroused state in the early exploration than in user-testing, reflection and pitch delivery. More specifically, in the beginning phases, Diver is physically and socially more stimulated, as shown in his dense laughter and high-pitched verbal expressions. In addition, clusters of disturbing moments within a person would emerge from the mapping over time. For designer Diver, the beginning phases of the design task are filled with positive disturbances as he interacts with the unfamiliar partner. The bodily signal graphs also show that Diver's disturbance-based learning peaks during the time of observing user behaviors through video materials.

In comparison to Diver, the video materials are less stimulating for some other designers with much fewer disturbing incidents. This observation allows us to revisit Diver to understand his knowledge and expertise, acknowledging his ability to see problems from what is otherwise perceived normal for other people. Figure 3 gives another example comparing Diver and Analyte, who was from another design team. Interestingly, Analyte's arousal stays low to medium throughout except for a few salient phases, such as the user-testing stage. Notably, Diver's arousal in the user-testing phase is low, whereas in the same phase it is highest for Analyte. In addition to possible individual differences in EDA, the differences can be better understood from analyzing their retrospective reflection. While Diver cares for keeping the energy up by immersing himself into the work, Analyte tends to detach himself from the design work as for him, "it was professional" and it was about applying "the process" and "rules of engagement".

As shown by these brief examples, meaningful interpersonal and intraindividual comparisons are made possible with the multimodal data of vocal pitch and EDA through contextualization and triangulation.

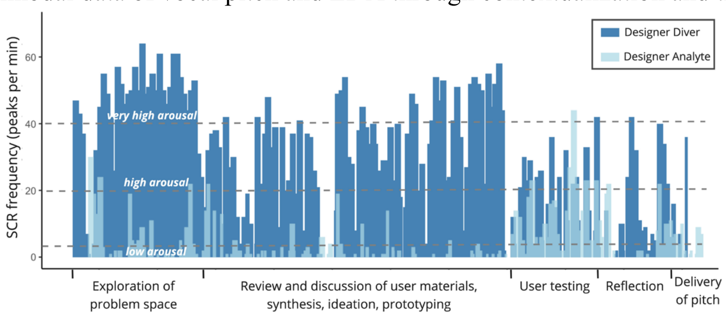

Figure 3. Comparison of designer Diver and Analyte who had distinctively different arousal profiles.

Discussion

How to capture, characterize and understand the knowledge-(re)construction process of experienced designers at disturbance? In pursuit of a methodologically rigorous approach, we integrate vocal pitch and electrodermal activity into the qualitative analysis of knowledge construction in situ. Such a mixed-methods approach enables researchers to study experienced designers' momentary emotional disturbances and situated knowledge work in the wild. As demonstrated so far, on the one hand, we are able to do micro analysis of how designers curiously chew on disturbances and adapt their assumptions in the moment and in context. On the other hand, it also gives a broader view of designers' learning dynamics across person and time.

Reflecting on the different measures of experience, we find electrodermal activity is sensitive to energy level and stress level, which is otherwise regulated in vocal expressions. In comparison, vocal pitch captures well involuntarily leaked momentary surprises (Detrich, et al., 2014), despite that most talking was well regulated with vocal pitches gravitating towards the mean. Meaningful phase-based segmentations of time-series data enable comparison of arousal level using mean and standard deviations. These objective measures have unique advantages and are complementary to traditional observational and self-report measures. It is otherwise difficult to see internal disturbances that are regulated in external behavior. Practically, participants in retrospect would not remember or voluntarily report exhaustively their swift disturbing experiences during a long activity, despite that the two given examples of knowledge construction process are quite emotional in situ. On the other hand, first-person perspective camera is promising for its unique advantage of approximating real-life observation and gives meaning to the lifeless physiological numbers.

We have applied some instrumentation and analytical tools from affective science. In affective science, however, scientists tend to avoid applying different measures due to poor concordance, as any one measure has its biases that are associated with variance unique to it (Mauss & Robinson, 2009). As a result, construct validity of arousal or stress is often unaddressed. In addition, EDA is sensitive to real-world noises when instrumented in the wild. Our study addresses the validity problem by approaching emotion arousal with contextualization and triangulation through multiple measures. This complexity-embracing approach, combined with basic bodily signal analytics, enables us to see discordance between different measures as opportunities to trigger new questions and new ways of data interpretation. Taken together, the current approach offers new and more comprehensive ways of seeing and understanding knowledge in action. Important questions going forward include how to capitalize on the technical conveniences for remote research given the challenges presented by the pandemic, and based on the current research insight, how to design coaching interventions to guide learners to navigate disturbances.

Conclusion

Designers, in the process of creative design, constantly construct their design thinking, feeling, behaving and learning. Adaptive design experts in particular exhibit extraordinary ability of reshaping knowledge and adjusting behaviors in situ — they learn as they design, in order to create new and meaningful products to solve peculiar problems at hand. In this paper we reflect on the past research of distributed learning in situ and propose new ways to advance this body of knowledge. We hope our research will open up fruitful discussions on how to advance learning sciences in the future. At the practical end, engineering educators are deeply concerned about bringing up next-generation designers to effectively, collaboratively and creatively deal with the complexities and uncertainties of the peculiar problems at hand. We hope the study will inspire educators to think about how to guide their students to curiously get disturbed, work on it and learn through it.

Scaffolds to Advance Revision in Science: Meta-Cognitive Knowledge About Revision Versus Generating Content Understanding

Katrina A. Bennett and Keke Kaikhosroshvili (shared first authorship)

Sarah Bichler, University of California, Berkeley, sbichler@berkeley.edu

Abstract: We examined whether knowledge about how to revise an explanation or opportunities to deepen content understanding support learners to revise their explanation of a complex science phenomenon. Learners in grades 6 to 10 (N = 147, M_{age} = 13.20, SD = 0.74) completed an online unit on Global Climate Change and were randomly assigned to one of three conditions (meta-cognitive scaffold, content scaffold, control condition without scaffold). An ordinal mixed-effects regression model showed that learners in the three conditions did not differ substantially in the quality of their revisions. An exploratory analysis indicated that whereas in the meta-cognitive condition the quality of learners' revisions was not related to their domain-specific prior knowledge, in the content scaffold and control conditions learners with higher prior knowledge produced better revisions. We discuss implications of these findings for practicing revision in science education and for future research.

Objective

Revision involves reviewing previously completed work and making changes to increase the completeness and accuracy of that work (Brownell et al., 2013; Tansomboon et al., 2017). When learners revise their explanations, they think more deeply about the learnt concepts which improves their understanding (Fitzgerald, 1987). Revising helps learners integrate their prior and newly learnt knowledge; a key aspect of forming coherent understanding (Linn et al., 2003). Scientists constantly engage in revision to improve their explanations of scientific phenomena, but students generally resist revising (Trevors et al., 2016). Often due to a lack of teachers' time, students also do not receive ample opportunity to engage in revision as a scientific practice during formal education (Beal et al., 1990). When asked to revise, students make superficial revisions like adding one word, or correcting grammar mistakes (Roscoe et al., 2013). When scaffolded, however, students make substantive revisions, such as elaborating an idea, adding new ideas, or correcting inaccuracies; this improves their explanations and consequently their understanding (Gerard & Linn, 2016; Roscoe et al., 2013). What is not yet understood is the exact effect that different types of scaffolds have on learners' revision behaviours. The present study investigated the relative effects of a meta-cognitive and a content scaffold compared to simply prompting learners to revise their explanations. It discusses the pedagogical reasons underlying the design of these different revision scaffolds to uncover whether learners benefit more from learning how to revise or from deepening their content understanding. Further, this study explores whether the benefit of different types of scaffolds depend on what a learner already knows.

Scaffolding revision of science explanations

Prior evidence

Previous research tested the effects of scaffolds such as critiquing others' work (Donnelly et al., 2015; Schwendimann & Linn, 2016), self-critiquing (Beal et al., 1990), revisiting evidence (Donnelly et al., 2015; Tansomboon et al., 2017), receiving peer or teacher feedback, making comparisons between one's own and an expert's work (Schwendimann & Linn, 2016), planning revision (Tansomboon et al., 2017), learning about revision strategies (Roscoe et al., 2013), and receiving additional domain-specific instruction (Gerard & Linn, 2016). Positive effects of scaffolds on revision were found in terms of the types of revisions learners made (superficial versus substantial) (e.g., Tansomboon et al., 2017) as well as in terms of improvements in the content from initial to revised explanations (e.g., Gerard & Linn, 2016).

Content and meta-cognitive revision scaffolds

One noticeable difference in the scaffolds designed to support learners' revision is that some scaffolds focus on supporting learners to understand the content in more detail while other scaffolds focus on supporting learners to understand what revision entails. For example, revisiting an animation to gain more detailed understanding of the scientific phenomenon that is to be explained can be viewed as a content scaffold (e.g., Donnelly et al., 2015). One reason for designing content scaffolds is to encourage learners to discover new aspects of a phenomenon, or new evidence to add to their initial explanation (Harrison et al., 2018). A simple prompt such as "Please review your explanation" may not be effective because learners most probably do not know what was missing in their initial explanation. In contrast, when guidance encourages learners to revisit evidence they used, they are more likely to generate new ideas that they can add to their explanation. Content scaffolds are also designed to support learners to discover discrepancies between their own explanation and other learning materials. For example, when learners critique a peer's explanation, they might notice that their peer misses a central piece of evidence or describes the phenomena inaccurately (e.g., Schwendimann & Linn, 2016). By providing feedback to the peer and then revising their own explanation, learners might check their own explanation against the advice they gave to the peer.

Although there is evidence that content scaffolds improve learners' understanding, teaching or revisiting content alone does not necessarily mean learners can recognize errors in their initial explanation (Ohlsson, 1996). Learners may need support to contrast their new and old ideas in order to recognize initial inaccurate ideas, refine and integrate them with the new ideas (Linn & Eylon, 2011), instead of just tacking on new ideas to the initial explanation (Harrison et al., 2018) while maintaining their inaccurate initial idea (Campbell et al., 2016; Clark, 2006; diSessa & Minstrell, 1998). This means that learners might not only need new ideas to make substantial revisions, but they also need strategies of how to revise their explanation (Roscoe et al., 2013). Meta-cognitive scaffolds are designed precisely to support learners to understand what they should or can do when asked to revise. Considering that learners do not often get the chance to revise their work (Beal et al., 1990), they might be unfamiliar with the process of revision. They might not know that they could search for errors by comparing their ideas with new evidence. Meta-cognitive scaffolds can provide strategies or give learners the chance to plan their revision (Roscoe et al., 2013; Tansomboon et al., 2017). For instance, worked examples are scaffolds that seem to lend themselves particularly well to fostering knowledge about revision. They have been used successfully to foster knowledge about argumentation by modeling the structure of an argument (Schworm & Renkl, 2007) and knowledge about how to collaborate by modeling collaborative sequences (Rummel et al., 2009).

The role of prior knowledge

Evidence implies that scaffolds need to align with learner's prior knowledge to be effective (Kalyuga, 2007; Snow & Lohman, 1984). Whether learners need deeper content understanding or knowledge of how to revise may depend on their prior knowledge. One could argue that a learner with less prior knowledge may not benefit from knowing how to revise as they do not have the content knowledge needed to add new ideas to their explanation. Learners with less prior knowledge may rather need to investigate more evidence to discover content ideas they can add. This assumption is based on prior evidence showing that learners with less prior knowledge benefit more from specific rather than general guidance (e.g., Renkl, 2014). For learners with more prior knowledge this would mean that they may rather benefit from meta-cognitive scaffolds that support them to refine their approach to revision as they already have the content knowledge needed for improving an explanation.

However, one could argue the opposite and assume that learners with less prior knowledge need to know strategies for revising; learning they can add ideas may guide them to seek out new ideas to add to their explanation (Wu et al., 2016). Not knowing what to do when revising might leave them attending to irrelevant aspects or ideas consistent with their explanation.

Additionally, previous research proposes that the level of engagement required by a scaffold will influence how learners with differing prior knowledge benefit from the scaffold. According to the ICAP Framework, activities which actively engage learners and encourage the manipulation of new information support learners who have less prior knowledge, whereas activities which encourage constructive engagement and knowledge generation better support learners with high prior knowledge (Chi & Wylie, 2014). Thus, whether a meta-cognitive or content scaffold is more effective for learners with less or more prior knowledge may depend on the scaffolds' affordances i.e., whether learners are engaged actively or constructively.

Research questions and hypotheses

We build on prior research and contribute to what is known about effectively guiding revision by experimentally testing what effect a meta-cognitive scaffold and a content scaffold have compared to a simple prompt to revise on learners' revision of a science explanation. We expect that students in the the meta-cognitive or content scaffold condition make more substantial revisions than students who are not supported (control condition).

Furthermore, we explore whether the effect of the meta-cognitive and content scaffold depend on learners' prior knowledge. Based on the discussed theories that point towards effects in either direction, we have no specific hypotheses as to whether the meta-cognitive or content scaffold is more effective for learners with less or more prior knowledge. In addition, we explore what students understand by the term revision in a qualitative analysis of student responses.

The present study including hypotheses and analysis plan was preregistered prior to the analyses on the Open Science Framework (OSF) (osf.io/yxa2k/). The learning unit used in this study, the coding schemes used to assess learners' knowledge and revision, and an anonymized data set including a variable documentation are openly shared on OSF once this paper is published.

Methods

Sample, design, and procedure

Four science teachers (one woman, three men) and their $N = 147$ learners (73 girls, 54 boys, 20 did not or preferred not to answer; $M_{age} = 13.20$ years, $SD = 0.74$) at secondary schools in the UK and Georgia participated in the study. These countries were used for recruitment because of researchers' familiarity with the education systems and/or the specific schools contacted. No compensation was given for participation. Data was used if the student and parent gave consent (UK) or if the student gave consent and parents did not object (Georgia). Researchers only had access to anonymized student data.

After applying exclusion criteria (detailed in results), a sample of $N = 66$ learners were included in statistical analyses (n = 50 in 8th, n = 16 in 6th – 10th grade). We used an online learning unit on Global Climate Change from the Web-based Inquiry Science Environment (WISE; Linn et al., 2003) and randomly assigned learners to one of three conditions: meta-cognitive scaffold (n = 24, 10 boys, 13 girls, $M_{age} = 13.09$, $SD = 0.75$), content scaffold (n = 19, 11 boys, 8 girls, $M_{age} = 13.41$, $SD = 0.71$), or control condition (n = 24, 9 boys, 14 girls, $M_{age} = 13.15$, $SD = 0.75$).

The study was administered slightly differently by each teacher, as teachers were free to choose the time frame of unit completion (ranged between 2 – 4 weeks), learners completed the unit at home on a device of their choice, and completion of the unit was voluntary. All learners received information about the study, were guided by teachers to create WISE accounts and log in to the unit, completed a pretest and then the unit.

Learning materials and scaffold conditions

The Global Climate Change unit covers how types of energy from the Sun transform and warm the Earth, how energy from the Sun interacts with greenhouse gases, and the greenhouse effect. Students explore how the human impact on the natural balance of greenhouse gases affects global temperatures and climate change. Students are engaged through various techniques: direct instruction, making predictions, observing evidence in interactive models, checking understanding with automated feedback, choosing variables of interest to investigate further, and writing explanations. Mid-way through the unit, learners were asked to "explain to Lea what role greenhouse gases play in how the Sun warms the Earth." Learners wrote an initial explanation and revised that explanation after the scaffold activity; in the revision step, an editable version of the initial explanation was imported.

Meta-cognitive scaffold

We designed a double content worked example, which guided learners step-by-step through 3 distinct revision steps: (1) adding ideas; (2) changing ideas; and (3) integrating ideas (Tansomboon et al., 2017). The example modeled the learning domain (revision strategies) using photosynthesis as the exemplifying domain (Schworm & Renkl, 2007). Learners could follow the thought process of a fictitious student James via thought bubbles that visualized James' thinking. The worked example modeled each revision step (add, change, integrate) and how James applied this step to his explanation about photosynthesis by highlighting the changes he made to his explanation (Figure 1). In the last step of the example James encouraged learners to revise their own explanation the same way he had revised his. Learners could move through the self-paced worked example multiple times.

Content scaffold

In an interactive workspace, learners dragged and dropped icons labelled 'Sun', 'Space', 'Surface of the Earth', 'Below the surface of the Earth', and 'Greenhouse Gases'; then added arrows to demonstrate the flow of energy between the elements in their diagram. Each arrow could be labeled with a type of energy ('solar energy', 'heat energy', 'infrared radiation'). When learners submitted their energy flow diagram, immediate, automated knowledge integration guidance was provided, which highlighted an inaccurate or missing aspect of the learner's diagram and directed them to revisit specific learning activities in the unit (Vitale et al., 2016). For example, when a learner inaccurately modeled that solar radiation was emitted from the surface of the Earth, the guidance prompted: “What type of energy is this? Where does it come from? Go back to the simulations in Step 1.6 and 1.7 to find out!” Learners were instructed to work on their diagram until they were told “Good job!”, but learners could themselves move on whenever they wanted. They could submit their diagram and receive automated feedback multiple times (see Figure 2).

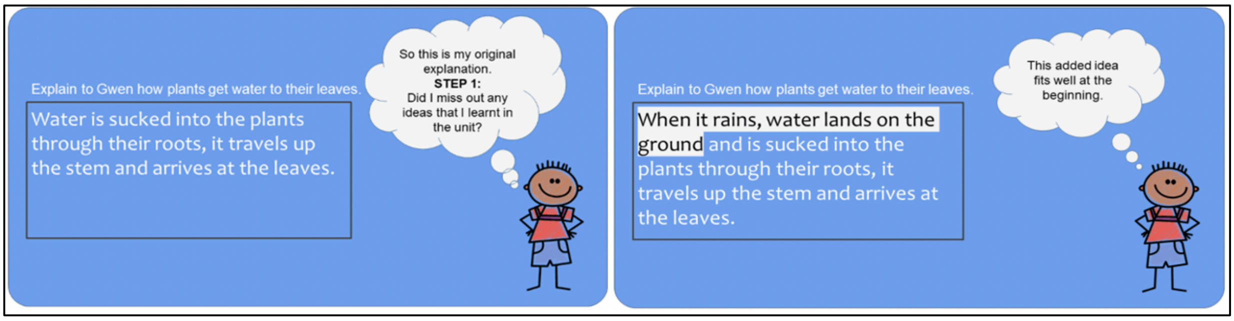

Figure 1. Meta-cognitive revision scaffold, modeling the revision step “adding ideas” via the exemplifying domain photosynthesis in a double content worked example.

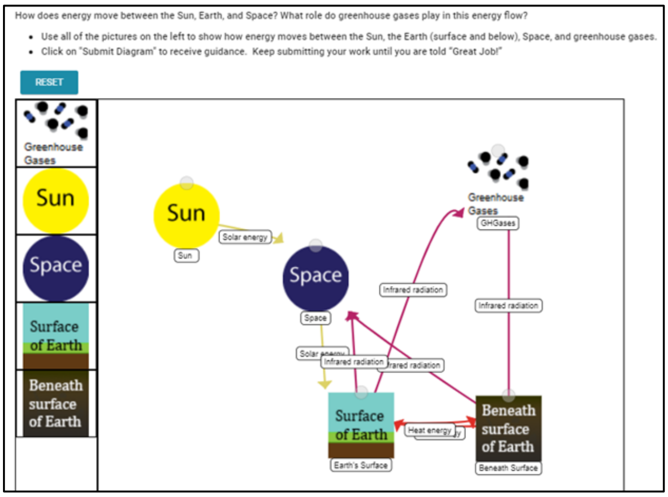

Figure 2. Content revision scaffold, demonstrating a learner’s energy flow diagram.

Control condition

Learners saw an editable version of their initial explanation and were prompted to revise with this prompt: “When we explain, we often don't include all our ideas. We often also realize that we didn't fully understand something when trying to explain it. Scientists often revise their work to refine their ideas and strengthen their explanations. This is your explanation to Lea. Think about whether you actually know more than you have written down and have a go at revising your initial explanation!”

Measures

To measure revision, we developed a rubric that assessed the type of change made from learners’ initial to revised explanation (Table 1). The rubric was adapted from prior research (Tansomboon et al., 2017). We first coded the initial explanation with a knowledge integration (KI) rubric and when the initial explanation received the highest score (5), we assumed that no condition would have an effect as there was no change the learner could make to improve their explanation. Initial explanations that received a KI score of 5 were excluded from the analyses. Two researchers coded 10% of all initial and revised explanations independently, resolved disagreements in discussion, and iterated this process until Cohen’s kappa was > .8. Then one trained researcher coded all data. The dependent variable revision is treated as ordinal variable in our statistical analysis as the rubric only allows ranking of the types of revision learners made.

We measured learners’ prior knowledge about climate change with five open response items, for example: “*Nina learned that life on Earth - humans, animals, and plants - can survive because the Earth's temperature is not too cold and not too hot. It is just warm enough to maintain life. Why doesn't the Earth overheat* *or get too cold and what could cause its temperature to get warmer and warmer?*" Each of the five items was coded using KI rubrics developed based on prior research (Bichler et al., 2019) that assess how well learners integrate ideas in their explanation (1 = inaccurate, vague or off-topic idea; 2 = accurate but isolated idea, no mechanism explained; 3 = inaccurate, vague, or incomplete mechanism; 4 = accurate mechanism; 5 = accurate and fully elaborated mechanism). Test items were coded as described for revision. A mean score across the five items was used as an indicator of prior knowledge (moderator and control variable).

We measured learners' understanding of the process and purpose of revision by asking them "Explain what you do when revising an explanation" and "What are some important reasons to revise your ideas in science?" Responses to these pretest items were analyzed qualitatively by identifying common themes.

Table 1: Revision rubric

Code	Description	Category of Responses
0	No revision needed	Initial explanation is complete and no changes were made
1	No revision	Initial and revised explanation are the same
2	Superficial revision	Words replaced, spelling errors fixed, or grammar changed Overall idea from the initial to revised explanation stays the same
3	Non-normative revision	Idea from initial explanation changed or elaborated, but idea is inaccurate
4	Substantive revision	Accurate ideas(s) added or inaccurate idea(s) changed to accurate ideas

Results

After excluding learners who did not consent, who had initial explanations with KI score 5, and who did not complete the revision step in the unit, there were $n = 24$ in the meta-cognitive, $n = 19$ in the content, and $n = 24$ in the control condition. After excluding one learner who did not complete the pretest, a sample of $N = 66$ was used for analyses.

Of students in the meta-cognitive scaffold condition, 67% made no revisions, as well as 68% of students in the content, and 71% of students in the control condition. To test our hypothesis that students who are supported with the meta-cognitive or content scaffold make more substantial revisions than students who are not scaffolded (control condition), we used an ordinal mixed-effects regression model. To control for the hierarchical data structure, a random intercept across teachers was added. We included prior knowledge (mean centered) as control variable in the model. We used the control condition as the reference group and included dummy variables for the two scaffold conditions (meta-cognitive and content) in the model. We found no statistically significant difference in revision for the meta-cognitive condition ($b = .59$, $z = .61$, $p = .272$) and the content condition ($b = .04$, $z = .06$, $p = .478$) compared to the control condition. The parameters from the model predict the chance that learners in each condition receive a particular revision score. Across all conditions, there was a low chance that learners substantively revised their explanation and received a revision score of 4, but this was more likely for those in the meta-cognitive condition (10%) than those in the content (6%) or control condition (6%). Learners in the meta-cognitive condition were also more likely to make a non-normative revision (revision score = 3, 22%), than those in the content (15%) or control condition (15%). The model predicted little difference in the chance of learners to revise superficially (revision score = 2) across all three conditions (10-13%). Finally, the chance of making no revision (revision score = 1) was predicted to be lower for those in the meta-cognitive condition (55%), compared to those in the content (68%) or control condition (69%). These model results hint that learners in the meta-cognitive condition were more likely than those in the content and control conditions not only of making a revision, but also of making more sophisticated revisions (non-normative and substantive). As the effects of conditions were not statistically significant, these results should only be interpreted descriptively.

Exploratory analyses

We explored the interaction effects between prior knowledge and the scaffold conditions by adding interaction terms for prior knowledge and meta-cognitive scaffold, and prior knowledge and content scaffold to the ordinal mixed-effects regression model. A visualization of the interaction between learners' prior knowledge and their revision scores in the three conditions is provided in Figure 3. We observed a significant main effect of prior knowledge ($b = 4.94$, $z = 1.86$, $p = .032$), indicating that in the control condition, learners with more prior knowledge showed higher revision scores. We observed a significant negative interaction effect between prior knowledge and the meta-cognitive condition ($b = -7.07$, $z = -2.07$, $p = .019$) indicating that the relation between prior knowledge and revision was less strong in the meta-cognitive condition compared to the control condition. A positive yet non-significant trend was observed in the interaction effect between prior knowledge and the content condition ($b = -3.66$, $z = -1.25$, $p = .106$), indicating that the relation between prior knowledge and students' revision score was also slightly less strong in the content condition than in the control condition.

To examine learner's understanding of the revision process we explored responses ($N = 73$) to the question "Explain what you do when revising an explanation". One researcher read all responses and noted common themes in students' reasoning. Some learners reported not knowing the answer to the question e.g., "I don't know what revising your ideas is supposed to mean". A variety of ideas about what steps to take for effective revision were expressed. For example, clarifying an explanation to communicate ideas better, finding and fixing mistakes, or learners mentioned that revision is a characteristic of "doing good science". Interestingly, the majority of learners understood revision as preparing for an exam. These students described revision as what you do when you revisit or memorize learning materials. For example, one student said "When i revise i make flashcards. i also read the explanation 10 times, say it 10 times and write it 2 times from memory, this helps facts and information remain in my head." We also explored $N = 80$ responses to the question "What are some important reasons to revise your ideas in science?" Learners seem to think that the main reasons to revise are finding and fixing mistakes, improving the quality of communication in science, better preparing for examinations, and staying up to date with the field of science. For example, one learner said, "Revising our ideas in science helps us to catch our mistakes if we made during the process". Another learner said, "To make it easier for other people to understand".

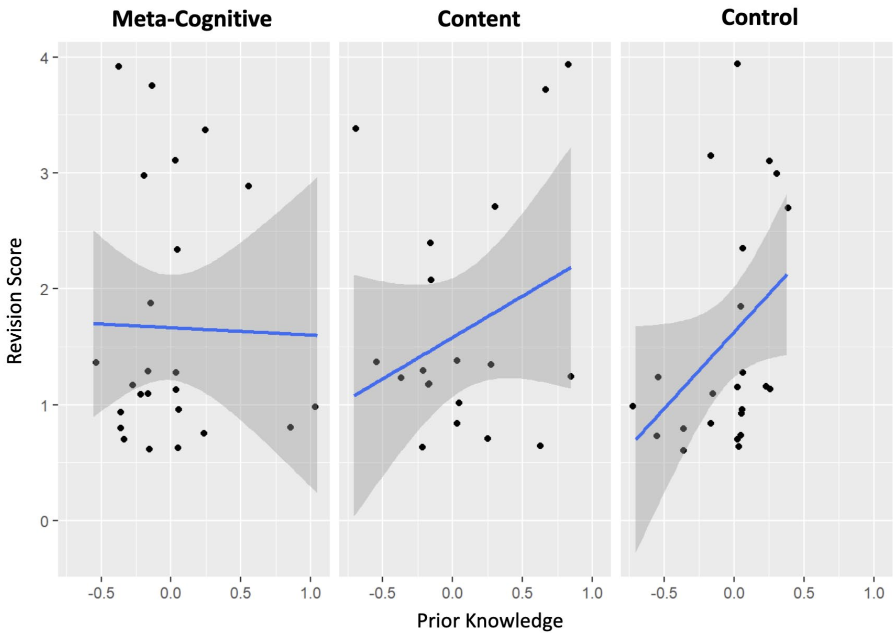

Figure 3. Graph demonstrating the interaction effects between prior knowledge (x-axis, z-standardized) and scaffold condition on revision score (y-axis). In the meta-cognitive condition (left), learners seem to be able to revise independently of their amount of prior knowledge, whereas in the content condition (middle) and particularly in the control condition (right), learners with more prior knowledge produce better revisions.

Discussion

We found that only about a third (31%) of students revised their explanation across all conditions. The remote learning situation and the fact that completion of the unit was voluntary could be the primary explanation for the low number of students who revised. We assume that had learners been in a classroom, their teachers would have encouraged them to put effort into revising their explanations. However, past studies in classroom settings found similar results (Donnelly et al., 2015; Trevors et al., 2016). Thus, we think that another explanation is that students are not socialized into a revision culture as revision is not a common classroom practice.

We found no evidence that the scaffolds led to more substantial revisions than the control condition, which could be due to the fact only a small percentage of students actually revised their explanation across all conditions. However, our control condition prompt may have been more than just asking students if they want to revise. It may have provided a decent explanation of why scientists revise and thus could be considered a meta-cognitive scaffold. A future study should use an even stronger control ("Please revise your explanation"). A trend was observed in the model estimates which proposed that learners in the meta-cognitive condition were more likely to receive a higher revision score, demonstrating more substantive revisions, than learners in the content scaffold or control condition. The explorative analysis of the interaction between prior knowledge and the scaffolding conditions showed that of the learners who did not receive guidance, those with more prior knowledge revised more substantively than those with less prior knowledge. Previous research suggests that learners who have accurate ideas before instruction are better at connecting old and new ideas than those with inaccurate initial ideas (Visintainer & Linn, 2015). We suggest to test this interaction effect with a larger sample.

Descriptively, it also seemed that learners with less prior knowledge made more substantial revisions when in the meta-cognitive than in the control condition, whereas for learners with higher prior knowledge the meta-cognitive versus control condition did not seem to make a difference. Also, learners with higher prior knowledge seemed to revise more substantively in the content compared to the control condition than did learners with less prior knowledge. These trends can only be interpreted on a descriptive level as our sample size was small and the observed trends are driven by a few learners in each condition. However, these trends provide the basis for further investigation of the interaction of prior knowledge and scaffolds for revision.

Potentially, for learners with less prior knowledge learning how to revise may be more beneficial, such that knowledge about revision is more helpful than deeper content understanding (Ohlsson, 1996). Similarly, learners with higher prior knowledge may benefit more from deepening their content understanding with scaffolds that activate their prior knowledge (McNamara et al., 1996) and help them link existing and new ideas.

Considering that the content scaffold required learners to generate a representation of their understanding, the problem-solving demands of this scaffold may have been higher than those of the worked example. In general, learners with higher prior knowledge benefit from scaffolds that require more problem-solving and learners with lower prior knowledge often struggle with high problem-solving demands (Renkl, 2014).

Moreover, the content scaffold likely engaged learners constructively as they were asked to generate knowledge and infer connections between the elements of their concept map (Chi & Wylie, 2014). Hence, it may have been better suited for learners with higher prior knowledge (Kaiser & Mayer, 2019). In comparison, the meta-cognitive scaffold likely engaged learners actively: it required learners to manipulate and apply the information modelled in the example. Therefore, this scaffold may have worked especially well for learners with lower prior knowledge.

Conclusion

We found that students are not likely to revise even when guided. Our results suggest that students know of many reasons why revision is important. Possibly, they are just not used to revising during and for learning. Instruction that emphasizes revision may establish revision as a common scientific practice. We emphasize that due to lack of statistical power this study by itself does not yet provide evidence that allows for a conclusion regarding the relative effectiveness of meta-cognitive and content scaffolds or the interaction with prior knowledge. However, this study provides a starting point for further investigating the question whether knowing about revision or learning new ideas about the phenomenon one explains is needed to revise one’s explanation and if what is effective differs for learners depending on their prior knowledge. As revision is not a common practice in classrooms, learners are likely also not introduced to revision strategies. However, this could be particularly important for learners with less prior knowledge in a domain. It is necessary to replicate this study with a larger sample.

Abstract: Online tutoring has become a primary instructional delivery method with increased global health restrictions. Providing effective communication strategies is critical in video lectures to reduce the physical gap between the tutors and learners for effective learning. Hence, this study presents empirical findings regarding the communication strategies of algebra tutors in online video lectures. We used two advanced psycholinguistic tools, Coh-Metrix and SÉANCE, to investigate how the algebra tutors explored different language choices with specific sentimental values. In addition, the different teacher-talk strategies were identified within levels of their pedagogical discourse marker use. The results revealed the importance of linguistic and sentimental indices to understand the communication strategies of the tutors providing instruction on various algebra topics. The findings further suggested that tutors tend to focus on providing intentional language cues in the form of pedagogical discourse markers to help build rapport with the learners in an online learning environment.

Introduction

The recent and sudden increase in demand for distance learning has raised interesting, but daunting questions for educators concerning delivery and evaluation methodologies in the realm of virtual learning. With highly restrictive regulations on in-person activities, a dramatic decrease of in-person exposure in all education activities is expected, including instructional activities. To provide an immediate solution to such problems, a large proportion of public and private education has moved to online modality. The instructions are provided using alternative interaction platforms, such as online tutoring and video lectures (Chick et al., 2020). Video lectures are one of the most widely used education strategies (Allen et al., 2002; Buckley & Smith, 2007; Choi & Johnson, 2005). Video lectures enable a boundless learning experience by allowing students to access the learning resources efficiently. Students can access and revisit the video lectures when needed, thus allowing students to learn at their own pace (Whatley & Ahmad, 2007; Brecht & Ogilby, 2008). Moreover, video lectures provide increased options for students to select the design, resources, and instructional styles based on their learning types (Lange & Costley, 2020).

In order to provide effective video lectures with such benefits, it is integral to ensure that the lecture content is delivered with clear and effective communication strategies (Costley et al., 2020). Effective communication is particularly important in video lectures to overcome the lack of human interaction in distance learning. Students commonly report feeling isolated in the distance learning environment as one of the biggest factors impacting their learning interest and motivation (Lee & Rha, 2009). Moreover, the lack of immediate feedback from the instructor paired with unclear instructions may induce confusion and frustration among students (Mayer, 2005). However, despite the concerns, there has been limited empirical research that understands and evaluates the effective frameworks of communication in video lectures (Breslow et al., 2013). In video lectures, educators are expected to communicate with the students using highly sophisticated teacher-talk strategies to facilitate more supportive and interactive environments to motivate the learners (Lee, 2010; Atapattu & Falkner, 2017). For instance, previous studies indicate that the tutor's intentional use of language to build social interaction with the students is integral to encourage effective student engagement and learning (Brame, 2016; Guo et al., 2014; Richardson & Swan, 2003).

However, while broad guidelines and suggestions have been presented by previous studies, there is still lack of empirical evidence to provide an in-depth understanding regarding how such teacher-talk strategies appear in various domains of online learning video lectures, such as algebra learning. Hence, the purpose of this study is to address this gap in the literature by analyzing the communication components in tutoring videos by investigating the tutor's communication component in lecture videos in terms of their psycholinguistic and pedagogical discourse characteristics.

To this end, we used psycholinguistic tools and natural language processing (NLP) augmented by theory-based discourse analysis. Our objective is to discover how intentional language choice in teacher-talk occurs in algebra video lectures, using the findings from the empirical dataset. As a result, this study focuses on understanding and evaluating how such teacher-talk strategies are used in online learning environments, in particular for Algebra Nation (Lastinger Center for Learning & University of Florida, 2019), an interactive algebra learning platform for grades 6-8 that includes video tutoring lectures. The following two research questions were addressed to guide the study: (1) Do tutors in Algebra Nation use different language strategies to establish better communication? If yes, what types of linguistic differences and strategies the tutors use to establish better communication in an online learning environment? (2) What types pedagogical discourse markers do tutors use to establish better communication?

Literature Review and theoretical background

Importance of Effective Communication in Video Lectures

Effective communication in video lectures reduces the physical gap between the instructor and students and overcomes the challenges that arise due to the lack of human interaction in distance learning (Lee, 2010; Atapattu & Falkner, 2017). Previous studies have emphasized the importance of instructors' communication strategies for enhancing effective learning in video lectures (Richardson & Swan, 2003; Guo et al., 2014; Brame, 2016). For instance, Richardson and Swan (2003) indicated that the communication style of the instructors in video lectures could have a significant impact on students' cognitive performance and their satisfaction. Similarly, Guo et al. (2014) suggested that the tutors' speaking style in the video lecturers is one of the important factors that impacts the effectiveness of video lectures. The empirical study focused on analyzing 6.9 million video watching sessions from courses on the edX MOOC platform to understand the effect of various factors on student engagement and learning outcomes. The findings suggested that students could engage better with talking-head videos. Students identified that talking-head videos are more "intimate and personal", thus, positively impacting their engagement. Also, students could engage more with video lectures when the instructor spoke faster. The study provided important insights to investigate the communication style of the instructor to increase lecture effectiveness. However, the suggestions were relatively limited to diagnostic recommendations regarding a tutor's language use for ideal communication styles in video lectures.

Pedagogical discourse marker framework

The role of strategic teacher-talk using discourse markers has long been emphasized in traditional classroom learning (Consolo, 2000; Morell, 2007). Fung and Carter (2007) introduced a comprehensive framework, which categorizes commonly used pedagogical discourse markers into four functional levels (Table 1). The comprehensive pedagogical discourse framework was designed to provide systematic structures of evaluation of such intentional instructional cues. The framework categorizes commonly used pedagogical discourse markers into four different functional levels: Interpersonal, Referential, Structural, and Cognitive. Each function focuses on providing a pleasant student learning experience by a) reducing social distance between a teacher and a student [interpersonal], b) providing grammatical connectives to the sentences [referential], c) signaling topic shift [structural], and d) denoting thinking processes [cognitive]. In the current study, we adopted the Interpersonal, Structural, and Cognitive categories to provide a customized evaluation and analytic framework of the tutors' communication strategies in the video lectures. The referential category was not adopted in the analysis as the category introduced discourse markers of low interest based on the primary research questions of the current study. In short, the functional paradigm of pedagogical discourse marker frameworks (Fung & Carter, 2007) was adopted to enhance the interpretability of the empirical findings from the natural language processing analyses.

Table 1: Functional Paradigm of Pedagogical Discourse Marker Framework (Fung & Carter, 2007)

Interpersonal Function	Structural Function	Cognitive Function
- Marking shared knowledge (e.g., *see, you see)* - Indicating attitudes (e.g., *well, I think*) - Showing responses	- Opening and closing of topics - (e.g., *let's start*) - Sequence (e.g., *first, second, next*) - Topic shifts (e.g., *how about*) - Summarizing opinions (e.g., *so*)	- Denoting thinking processes (e.g., *well, I think, I see*) - Reformulation & self-correction (e.g., *I mean*) - Elaboration (e.g., *for example*) - Hesitation (e.g., *well, sort of*) - Assessing learner's knowledge

(e.g., *okay, yeah, great, I see*)	- Continuation of topics (e.g., *yeah, so*)	(e.g., *you know*)

Methods

Data

We analyzed 125 video lectures by five tutors collected from Algebra Nation. Algebra Nation is an online learning platform, which provides free learning resources to students and teachers. The learning contents in Algebra Nation follow the core standards for Algebra 1 in the designated state to provide effective algebra learning modules, such as online practice tools, interactive wall post, and dynamic video lectures. In the current study, we analyzed the video lectures, which included 25 topics from three main algebraic concepts introduced by each instructor. The lectures spanned between 10.7 and 22.0 minutes (M=17.2; SD=5.0). The video content was designed to follow the same algebra workbook content. The workbook content introduced algebraic concepts and practice questions to help improve student learning[1]. Given that the videos covered the same workbook content, we hypothesized that the differences in the videos' length stemmed from the varying problem-solving and communication strategies used by the tutors. As such, we focused on analyzing the communication strategies geared towards engaging and motivating students, referred to as the "communication" component in the following sections.

Analysis Framework

The analysis was conducted in three stages to investigate how teacher-talk strategies were employed in video lectures from Algebra Nation. In the first stage, the video lecture transcripts were parsed into three categories based on their content. This was to identify and extract the "communication" component from the video transcripts, which served as the primary focus of the current analysis. The other two categories included the "workbook" and "lecture" components. These components referred to the parts of the text where the tutor rephrases the workbook content and explains algebraic concepts or solutions. The second stage of the analysis focused on understanding the differences in language use in the communication component among the tutors using the psycholinguistic features. We extracted an extensive list of psycholinguistic indices from the communication content of the video lecture transcripts using Coh-Metrix (McNamara et al, 2014) and SÉANCE (Crossley et al., 2017). Then, we used the Random Forest classifier to investigate whether the psycholinguistic features could accurately classify the tutors. The feature importance indices were inspected to understand the relative contribution of the variables to the classification outcome. In stage 3, we focused on understanding the differences in the tutor's language by identifying and comparing pedagogical discourse markers. This was achieved by extracting discourse markers using n-gram-based clustering. We then identified the discourse markers patterns used by each tutor. The findings from the last two stages of the analysis are described and explored thoroughly in the Results section.

Results

Differences in the Language Use and Sentimental Component

A total of twenty-six features were identified to provide deterministic information to classify the algebra tutors based on their communication language use (Random Forest (RF) Classifier, accuracy on the test set=86.7%). The final feature set included fourteen sentiment component scores from SÉANCE and twelve Coh-Metrix indices. Tables 2 and 3 and Figure 1 provide detailed descriptions of the SÉANCE and Coh-Metrix indices included in the final model. More specifically, four specific categories of Coh-Metrix indices were located to have high classification power. The four categories included, "Word Information", "Text Easability", "Syntactic Pattern Density", and "Situation Model". The word information index (WRDPRP1p, "First-person plural pronoun incidence") shows the highest contribution (8.9%) to accurately classify the communication components in video scripts based on tutors. This suggests the frequency of tutors using words, such as "we" and "us" could work as a good indicator for differentiating communication components among the tutors. Also, the polysemy for content words (2.6%) and verb incidence scores (4.3%) were identified as deterministic variables from the word information category. Polysemy for content words identifies the average number of distinct meanings the word represented. Hence, it is often highly related to the ambiguity of text due to the larger room for varying interpretations. This suggests the varying level of ambiguity of the communication component could help differentiate the teacher-talk among the algebra tutors. Similarly, the tutors' communication components could be differentiated using their text easability measured by narrativity (3.7%), verb cohesion (3.4%), syntactic simplicity (3.2%), and connectivity (2.6%). This suggests the varying level of difficulty, or easability, of the communication of the tutors as an important indicator to differentiate their teacher-talk strategies. In terms of the syntactic pattern density features, the noun phrase density score (4.6%), expanded temporal connectives incidence score (3.7%), and the preposition phrase density score (3.5%) were identified as deterministic features. Lastly, one feature was identified as significant in the situation model category. This category of features represents the level of mental representation of the readers based on the content provided in the text. Specifically, the intentional content features (3.7%) attempt to understand the "intentional actions, events, and particles" provided in the text (McNamara et al., 2014, p.66). Hence, our findings indicate that the tutors' use of intentional language in the communication content significantly identifies the varying teacher-talk strategies among the algebra tutors (Figure 1, Table 2).

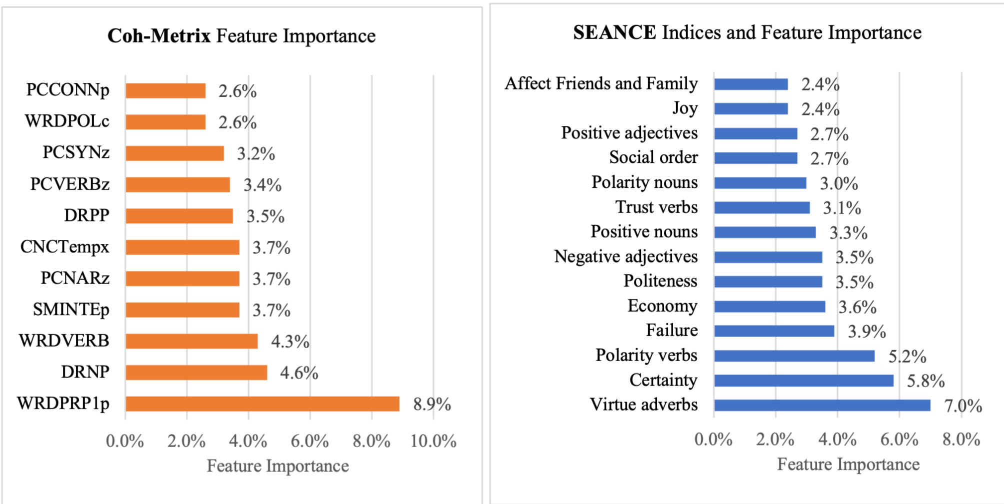

Figure 1. Final Random Forest classifier feature importance of the top 25 Coh-Metrix and SÉANCE features

Table 2: Final Random Forest Feature Importance of Coh-Metrix Indices

Category	Index	Description	Importance (%)	Total (%)
Situation Model	SMINTEp	Intentional content	3.7%	3.7%
Syntactic Pattern Density	DRPP	Preposition phrase density	3.5%	11.8%
	NCTempx	Expanded temporal connectives incidence	3.7%	
	DRNP	Noun phrase density	4.6%	
Text Easability	PCCONNp	Connectivity	2.6%	12.9%
	PCSYNz	Syntactic simplicity	3.2%	
	PCVERBz	Verb cohesion z score	3.4%	
	PCNARz	Narrativity	3.7%	
Word Information	WRDPOLc	Polysemy for content words	2.6%	15.8%
	WRDVERB	Verb incidence	4.3%	
	WRDPRP1p	First person plural pronoun incidence	8.9%	

The SÉANCE indices thus identified how the varying language choices conveyed different sentimental values in the algebra tutor's communication component. The final 14 indices from SÉANCE included various component scores regarding virtue adverbs, certainty, polarity verbs, failure, economy, politeness, negative adjectives, positive nouns, trust verbs, polarity nouns, social order, positive adjectives, joy, and affect friend and family. Table 3 provides detailed information on the description and the importance of each component score with example words. Given the current dataset contains the communication component of algebra video lectures, the findings provide important insights regarding the types of words tutors differentially select to communicate with the students differently. More specifically, the use of adverbs related to virtue (7%), certainty (5.8%), and failure (3.9%) showed relatively high contributions to the classification outcomes. To summarize, the random forest feature importance outcomes with psycholinguistic features from Coh-Metrix and SÉANCE indicated the varying word selection in communication components among the tutors. The findings suggest that the intentional choice of words, measured by the word information, the syntactic structure, and the text easability indices, varied significantly among the tutors. Also, the various sentiment behind the word choices were identified as an important factor differentiating the communication components of the five algebra tutors.

Table 3: Final Random Forest Feature Importance of SÉANCE Component Scores

Component	Description & Importance	
Virtue adverbs	Nouns related to worship and forgiveness (e.g., *blame, conviction, earn*)	7%
Certainty	Words indicating "a feeling of sureness, certainty, and firmness" (e.g., *absolute*)	5.8%
Failure	Verbs indicating power decreasing (e.g., *attack, banish, beat*)	3.9%
Economy	Words related to economy (e.g., *account, affluence, agricultural*)	3.6%
Politeness	Words concerned with a tools or forms of invoking formal power (e.g., *civil*)	3.5%
Negative adjectives	Negative adjectives (e.g., *abject, abrasive, abominable*)	3.5%
Positive nouns	Positive nouns (e.g., *acceptance, abundance, accomplishment*)	3.3%
Trust verbs	Words describing the state of trust (e.g., *admire, adore, anticipate*)	3.1%
Social order	Words concerning social order (e.g., *adhere, appall, corrupt*)	2.7%
Positive adjectives	Positive adjectives (e.g., *absorbent, able, accessible*)	2.7%
Joy	Words related to joy (e.g., *superb, affection, complement*)	2.4%
Affect Friends and Family	Nouns related to friends and family (e.g., *brother, company, friend)*	2.4%

Pedagogical Discourse Marker Identification

We next identified how such differences in word use or language use in communication components occur differently for each tutor using pedagogical discourse marker clustering analysis. Unlike the previous analysis, the findings from the pedagogical clustering analysis can potentially reveal the explicit differences in pedagogical language use among the tutors. Seventeen pedagogical discourse marker clusters were identified using K-means clustering analysis of 6,119 sentences belonging to the "communication" components. The final model used tf-idf vectorization with n-grams ranging from 1 to 5. The k-means clustering results identified a number of interpretable discourse marker cluster categories. However, we also noted a non-negligible proportion of samples indicating relatively unclear results (18.9%). This could be largely due to the noisy structure of the text data.

While the results located interpretable groups of pedagogical discourse markers, it was necessary to provide theoretical support to decipher their core functional roles in teacher communication. As a result, the final set of discourse marker clusters was evaluated using Fung and Carter's (2007) framework. Table 4 provides the final discourse marker identification results that are organized based on the discourse marker function framework. This framework identifies the core functional category of pedagogical discourse markers using the primary functions, such as the "interpersonal", "structural", and "cognitive" functions (Fung & Carter, 2007). A mapping was found for each cluster by locating the best-fitting category based on the pedagogical function. The resulting categories consisted of seven specific discourse function categories.

Table 4: K-means Clustering Results based on the Pedagogical Discourse Markers by Fung & Carter's (2007)

Core Functional Category		Discourse markers	Cases (N)
Interpersonal Function	Marking shared knowledge	*we are close; we are almost there*	45
		we know that; we know what to do; we have this to solve	145
		That is what is happening; that is what is up; that is how we do	188
	Indicating Attitudes	*This is very important; you should be careful; this is a bit tricky.*	98
	Showing Responses	*That is good; that looks good; awesome job*	312
		Ok, that is cool; cool; alright; all right; fantastic	1,459
		That is true; that is incorrect; yes; no	386
		There you go; here you go; just like that; there it is.	190
		you got this; you guys are smart; keep studying hard	178
Structural Function	Opening and closing of topics	*Hi everyone; hey Algebra Nation*	128
		Thank you; I will see you next time; see you in the next video.	140
	Topic Shifts	*Let's see; let's take a look; let's jump in*	855
		It is up to you; you can do either way.	214
Cognitive Function	Denoting thinking processes	*We are going to; you are going to; you will; we will*	326
		Same thing applies here; same idea here	131

		Sorry; sorry about that	32
	Assessing listener's knowledge	*Thinking about this; what about this; you know what?*	136

The findings indicated that the majority of the pedagogical discourse markers served interpersonal functions (Table 4). Pedagogical discourse markers from interpersonal functions focus on reducing the physical gap between the tutors and the students by indicating "shared knowledge component", "providing tutors' attitudes about the topic explicitly", and "providing immediate feedback and responses". Also, a number of discourse markers were identified from the structural function. These markers suggest that the algebra tutors in the current dataset intentionally provided cues to help students feel that lecture contents are organized and structured. Lastly, two pedagogical discourse makers of the cognitive function were discovered, which attempt to "denote thinking processes" and "assess students' knowledge". The cognitive function discourse markers indicate that the algebra tutors tended to challenge students by assessing the student's level of understanding regarding the lecture content. Additionally, the findings indicate that the tutors consciously communicate the lecture content by explaining their thinking processes to students for effective learning experiences.

Conclusion and discussion

This study aimed to understand the teacher-talk strategies in the communication component from video lectures focusing on algebra content. We focused on identifying the deliberate use of word choices in video lectures and the sentiment behind those word choices in video lectures. The findings from our first analysis suggested that the word information, easability, and narrativity of the tutor's speech, and the intentional verb choice in the communication component of the lecture videos showed distinct differences between the tutors. The results reinforced the suggestions from the previous literature, which highlighted the importance of word choices in building social partnership with the students through careful and intentional word choices (e.g., first-person plural, intentional verbs, easability of text). Moreover, the tutors' intentional language choice significantly varied in terms of the primary sentiment conveyed in their communication component. While the previous literature emphasizes the importance of particular sentimental values, such as "enthusiasm" and "excitement" in the tutor's communication component, the current findings discovered how the varying types of sentimental values are incorporated in the tutors' communication component, such as "virtue", "certainty", and "failure".

In our second analysis, we investigated how specific language choices occur in the form of pedagogical discourse markers in tutors' communication components. Pedagogical discourse markers are intentional language cues that the tutors provide to convey various functions in instructional conversation (Fung & Carter, 2007). For instance, adequate use of pedagogical markers could help build interpersonal communication ("interpersonal function"), help structure, and organize the lecture contents ("structural function") and encourage activation of cognitive processes ("cognitive function"). We discovered 17 different types of pedagogical discourse markers from the tutors' communication component in algebra video lectures. The majority of the discourse markers served the "Interpersonal" function, which focuses on reducing the physical gap between the instructors and students by "marking shared knowledge', "communicating tutors' attitudes" and "showing responses to students". Similarly, a number of discourse markers focusing on "structural" and "cognitive" functions were incorporated by the tutors to help structure the video contents, to let students denote thinking processes, and to access the learner's level of understanding. Moreover, the five algebra tutors showed distinct patterns in the use of discourse marker functions to covey video lectures on various algebra topics. Three different patterns of discourse marker function combinations were identified. Tutors tended to adopt the pattern representing the dominant use of discourse markers with interpersonal functions to "show response to provide immediate feedback to students. The findings in our study provide important implications for understanding and evaluating the tutors' communications strategies in video lectures with theoretical contributions. Our findings provide new insights into how the intentional use of language in communication components occurs in real-life video lectures. The mixed-methods investigation has strong potential to provide important insights on how intentional language choice, the sentimental value of language, and the pedagogical function of the language vary in tutoring videos. This finding affords a more complete list of suggestions and recommendations for effective communication strategies in video lectures.

Abstract: We articulate a framework for characterizing student learning trajectories as they progress through a scientific modeling curriculum. By maintaining coherence between modeling representations and leveraging key design principles including evidence-centered design, we develop mechanisms to evaluate student science and computational thinking (CT) proficiency as they transition from conceptual to computational modeling representations. We have analyzed pre-post assessments and learning artifacts from 99 6th grade students and present three contrasting vignettes to illustrate students' learning trajectories as they work on their modeling tasks. Our analysis indicates pathways that support the transition and identify domain-specific support needs. Our findings will inform refinements to our curriculum and scaffolding of students to further support the integrated learning of science and CT.

Introduction

The Next Generation Science Standards (NGSS; NGSS Lead States, 2013) identify modeling as one of the eight science and engineering practices that prepare students for the 21st century workforce. Modeling enables students to generate, integrate, and test theoretical ideas (Lehrer & Schauble, 2015), providing authentic experiences that deepen students' understanding of scientific phenomena. The practice of modeling is also central to the discipline of computer science (CS) (e.g., K-12 CS Framework (2016)). Integrating science and CS has compelled researchers to develop frameworks guiding their synergistic learning in K-12 classrooms (e.g., Sengupta et al., 2013; Weintrop et al., 2016). While educational policy promotes the integration of CS practices as part of science instruction, little guidance is provided on how teachers may support students in meeting these expectations across disciplines (e.g., NGSS Lead States, 2013).

Technology-enhanced environments can scaffold students in computational modeling processes that engage inquiry and problem solving (e.g., Jonassen, Strobel, & Gottdenker, 2005; Keating et al., 2002; Sengupta et al., 2013; Weintrop et al., 2016). Computational modeling experiences need to be anchored to strong underlying conceptual models of the phenomena being investigated in order to leverage the unique affordances of both conceptual and computational model representations. Together, conceptual and computational representations provide a more complete depiction of phenomena and support students in deriving linkages between model representations (Frederiksen et al., 1999). Limited research describes how students make transitions and connections among model representations and identifies the instructional supports they require.

In this paper, we focus on middle school students' learning of science and computational thinking (CT) as they engage in modeling tasks over the course of a 3-week curriculum unit integrating Earth science, engineering design, and CT (Chiu et al., 2019). Our approach centers on understanding students' ability to model the Earth science concept of water runoff by working through a sequence of representations from conceptual to computational modeling. Our study addresses the following research questions: (1) How do we characterize students' learning trajectories from conceptual to computational modeling? and (2) How do the different modeling vignettes that students generate along this trajectory relate to one another and show students' learning of relevant science and CT concepts?

Theoretical and empirical foundations

Supporting scientific modeling using conceptual and computational representations

Scientific modeling enables students to delve deeper into understanding phenomena by explaining and predicting system behavior (Schwarz & White, 2005). Examples of common conceptual models in K-12 science education include models of food webs, planetary orbits, and the water cycle. Recently, there have been efforts to introduce computational modeling methods to help students gain a better understanding of scientific phenomena (e.g., Sengupta et al., 2013; Weintrop et al., 2016). Computational models provide explicit mechanisms for constructing and visualizing phenomena, reasoning about scientific processes as a sequence of events (as opposed to creating aggregated mathematical models), and providing explicit opportunities to study step-by-step changes in model behavior (versus continuous dynamics). Moreover, computational models of scientific phenomena help to contextualize complex CT concepts (e.g., conditional logic) to support CT learning.

However, research has identified that students may have significant difficulties with developing computational models in science. For instance, students may struggle to understand the science concepts underlying their computational models and to represent system variable relationships computational expressions (Sengupta et al., 2013). These challenges may stem from students' difficulty in identifying model components, interactions among components, or the underlying scientific principles underlying the model (e.g., Forbes, Zangori, & Schwarz, 2015). Students may have trouble generalizing or abstracting the scientific processes into variables and expressions (Basu et al., 2016). These findings indicate a need to anchor the design of computational modeling tasks to conceptual modeling activities and to examine the types of support students may need to make the transition from conceptual to computational models.

For effective participation in this important STEM practice, students and teachers need support as they grapple with the dual complexities of scientific and computational modeling. There is limited research that examines how students' science and CT knowledge evolves over the course of a computational modeling unit that introduces science and CT concepts and practices. Additional research can advance understanding of the synergistic relation between science and CT and how learning in each discipline supports and/or impedes learning in the other. These insights will in turn help scaffold integrated learning of the underlying science and CT concepts. In this paper, we analyze students' learning artifacts as they develop a sequence of models of water runoff to examine how instruction can help students transition from conceptual to computational models.

Design perspectives

We integrated three design perspectives in developing an integrated science + CT computational modeling unit:

- **Evidence-centered design (ECD)** - We use ECD (Mislevy & Haertel, 2006) to analyze the integrated science + CT domain, systematically unpack the target science and computing concepts and practices, and identify connections between the science and CT views of the modeling practice. ECD helps designers link the features of instructional tasks and assessments to evidence of students' proficiency with the target knowledge and skills. In this case, we aim to promote both science and CT-oriented modeling proficiency across evolving modeling representations.
- **Maintain coherence across system representations** - In order to address novice students' difficulties in deriving links among the evolving representations, the conceptual coherence needs to be made explicit (Ainsworth, 2006; Frederiksen et al., 1999). For instance, in this study, each of the evolving modeling representations makes explicit the conservation relationship among rainfall, absorbed water, and water runoff at different levels of abstraction and generality.
- **Domain-specific modeling languages (DSMLs)** - We have created a DSML to make it easier for students to express their scientific understanding of the science concepts and relations into a set of computational constructs that model the science phenomena (e.g., water runoff) (Hutchins et al., 2020). DSMLs enable students to place greater focus on the science concepts and system variables without having to attend to the details of program construction.

Overall, we hypothesize that the three design perspectives will support students as they work through the linked modeling representations from conceptual to computational, thus reducing the difficulties they face in integrating science and CT modeling concepts.

Curriculum description

The Water Runoff Challenge (WRC) is a three-week, NGSS-aligned unit that challenges students to redesign their schoolyard using different surface materials to minimize the amount of water runoff after a storm while adhering to a series of design constraints. These include the overall cost and accessibility, while providing for different functionalities for the schoolyard (Chiu et al., 2019). The WRC targets NGSS performance expectations for upper elementary Earth science and engineering design curricula, emphasizing the movement of surface water in a system after heavy rainfall and the human impact of this runoff on the environment.

Figure 1 illustrates our designed learning trajectory and criteria from conceptual to computational model construction. Initially, students were expected to apply the matter conservation principle (science concept): Total rainfall = total absorption + total runoff, through the construction of paper-and-pencil conceptual models. Each subsequent modeling form required application of additional CT concepts to specify the model in a more general form (see Figure 1). To support this, we implemented an intermediate paper-and-pencil Rule Creation task (Figure 2(b)) to elicit an additional representation of the science phenomenon enabling students to express the relation between the science concepts: total rainfall, total absorption, absorption limit, and total runoff. Students are tasked with expressing three scenarios (i.e., when rainfall is greater, less than, and equal to the surface absorption limit) as semi-structured rules. These relations take into account the conservation laws while using conditional logic expressions to specify when different situations apply (e.g., no runoff versus a certain amount of runoff). Students then transfer their rules into a computational model using the given DSML blocks to create the model components (i.e., the three rules). Translating the rules to the computational modeling activity requires additional knowledge of variables and mathematical and relational operators. We detail each activity, below.

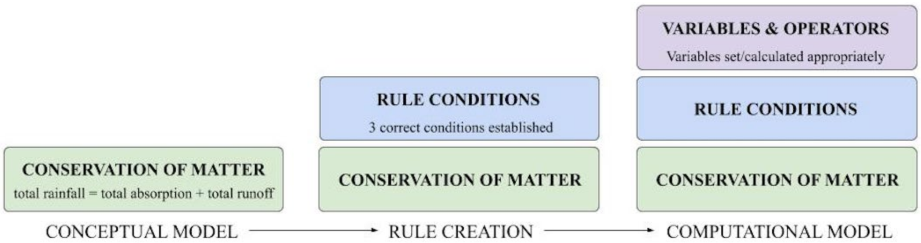

Figure 1. Learning trajectory from conceptual to computational model tasks.

In the WRC, students are introduced to the science concepts of matter conservation and the absorption characteristics of different surface materials. Students then develop pencil-and-paper conceptual models that express the amount of water runoff in terms of the total rainfall and water absorbed by the different materials. As a first step to understanding runoff, students use paper and pencil to generate an input-output model that includes rainfall, absorption, and runoff. Students can describe the conservation relation numerically, pictorially, and/or through a descriptive written response. For instance, to complete Figure 2(a), students are tasked with predicting the amount of absorption and runoff for 3 inches of rainfall and a 1-inch absorption limit of the surface material. As a second step in the model evolution process, the students then create a more precise conceptual model on paper, where they create rules to describe the three different runoff conditions.

After additional scaffolding, where students practiced writing conditional constructs in an unplugged activity (the Rule Creation task, Figure 2(b), described above), the students created their computational runoff model in the computational modeling environment using DSML constructs (Figure 2(c)) that facilitate the translation of the runoff rules into the computational model (Chiu et al., 2019). Example student models appear in the Findings section (Figure 3). The DSML blocks help students assign variables to specific values, and translate their runoff rules to "if" constructs (e.g., "if total rainfall is greater than the absorption limit", then "set total runoff to [total rainfall ⊠absorption limit]"). Students also needed to assign the value of total rainfall and the absorption limit before the conditional block statements. After students constructed a working computational runoff model, they could study the effects of different surface materials on runoff from the schoolyard to the surrounding area.

In designing each of the model building activities, we maintained coherence across the three representations, and gradually introduced students to CT concepts and practices. This approach provides a framework for evaluating students' modeling artifacts across different representations and how these representations support students' learning trajectories.

Figure 2. Task examples for paper-and-pencil conceptual modeling (a) and rule creation (b), and the DSML used for the computational modeling task (c).

Methods

We conducted a three-week classroom study with 99 sixth-grade students in the U.S. using the WRC. All participating students had some prior programming experience with block-structured programming using Scratch (Maloney et al., 2004). The participating teachers were experienced science teachers and received four days of professional development before the study. Three researchers provided additional support but mostly acted as observers during the study. Students worked for 45 min per day, three days a week during their regular science classes, and 75 min, twice a week with additional personalized-learning time.

Data sources, scoring, and analysis

We examined three primary types of student data: paper-based artifacts, students' final computational models, and a pre-post assessment. All tasks evaluated for this paper were completed in class.

Students' paper-based **Conceptual Models** were coded based on whether their representation of the conservation of matter principle (see Figure 1) was *mechanistic* (and correct), *numeric* (and correct), or *developing*. In order to achieve a *mechanistic* score, students were required to show or use text (via pictorial or descriptive representation) the causal relations resulting in the division of the total rainfall into absorption of water and the amount of runoff using a correct algebraic or numerical expression. A *numerical* score indicated the representations showed all of the required elements and correct values, without describing the causal relations. A *developing* score reflected misunderstandings or errors in students' application of the conservation of matter principle. Students' numerical, pictorial, and written descriptions were coded separately, and students' understanding was represented by the highest score they received on a single part.

For the **Rule Creation** task, each rule that students developed was scored separately. For Rule Conditions (see Figure 1), students received scores for expressing the correct conditional relation between total rainfall and absorption limit (e.g., if total rainfall is greater than the absorption limit). The conservation relation was scored for a correct expression of the values for each required output: total absorption and total runoff.

Students' **Computational Models** were scored using a predefined rubric targeting the application of the conservation of matter rules, the conditional statements for the different rules, and the variable assignments (for rainfall, absorption, runoff). The maximum score possible is 15. To achieve that, students had to assign appropriate values to total rainfall and absorption limit, generate the code for the three conditional statements based on a comparison of variables (total rainfall and absorption limit) and update the absorption and runoff variables for each of the three conditions. Students were given points for generalizability only if they used expressions comprising variables and operators to express variable values (e.g., setting total runoff to "total rainfall ⊠ absorption limit" in the overflow condition) as opposed to just assigning numeric values to variables.

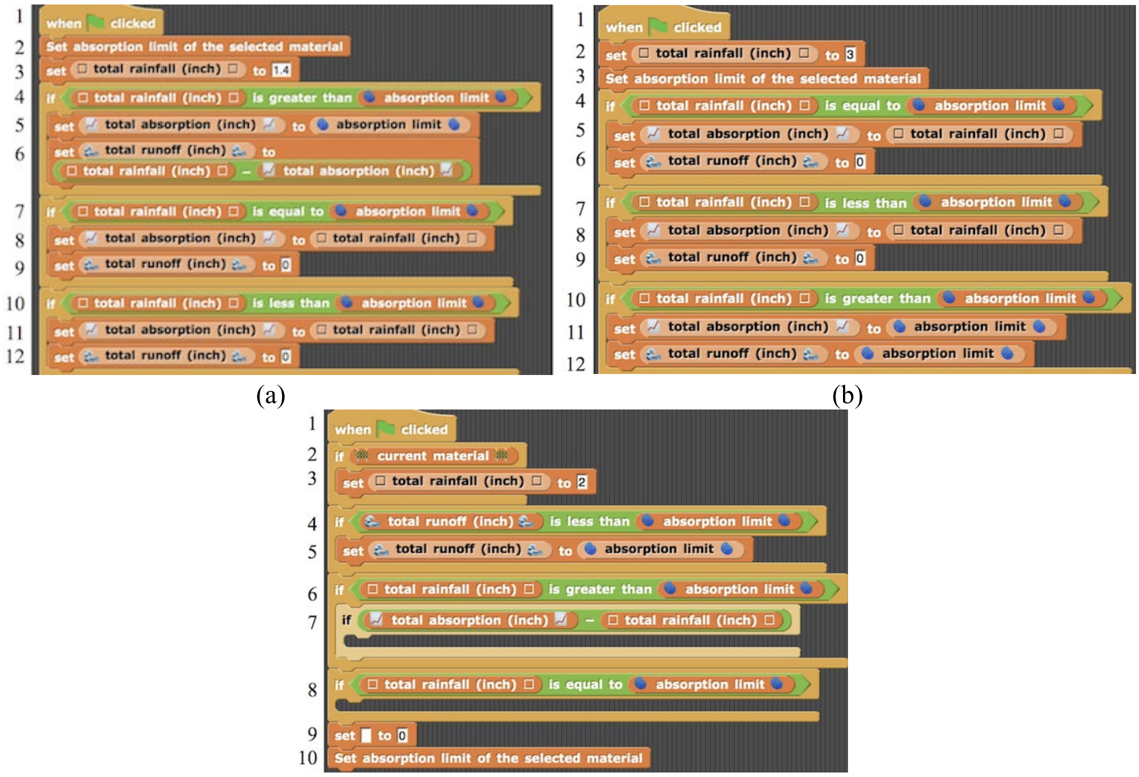
Students completed a paper-and-pencil **pre-post assessment** that was split into a science and engineering component and a CT component. Our science and engineering pre-post assessment aligns with a number of NGSS Performance Expectations (PEs). Students could get a maximum score of 23 points. The CT assessment tasks were aligned with the concepts and practices addressed in the modeling activities (e.g., variables, operations, conditionals, program development) and had a maximum score of 13 points. The rubrics used for coding and scoring these assessments were updated from our previous work (McElhaney et al., 2019). Two researchers received 5 hours of training on the rubrics, graded 5% of the test submissions (randomly selected) together to establish initial grading consistency, and then graded another 20% to establish inter-rater reliability (Cohen's κ at ≥ 0.8 level on all items). All differences in the coding were discussed and resolved before the remaining 75% of test submissions were graded by a single researcher.

To answer our research questions, we summarize class learning trajectories through correlation analysis and present three contrasting student vignettes (with pseudonyms Alex, Marley, and Taylor). Where appropriate, we position the performance of these three students relative to the range of student performances we observed.

Findings

Summary of student performance on modeling artifacts and pre-post assessments

Students successfully completed the WRC as intended. Pre-post assessment scores were determined to be normally distributed and a paired t-test analysis showed significant learning gains in science and engineering ($p < 0.0001$, Cohen's $d = 0.82$) and CT ($p < 0.0001$, Cohen's $d = 0.83$). We classified 32 students' Conceptual Models as mechanistic, 59 as numerical, and 7 as developing (1 student packet missing). For the Rules Creation task's Rule Condition component, 57 students correctly described the three conditions while 35 had errors in at least one rule condition (remaining responses were either illegible or missing). For the conservation of matter component, 35 students correctly calculated both absorption and runoff for each rule with 63 students incorrectly calculating or missing elements (1 student packet missing). The main issue with the conservation of matter performance during rule creation were missing variable assignments for either runoff or total absorption in each condition (e.g., students would only describe the resulting runoff when describing what happens when total rainfall is greater than the absorption limit). The Computational Model mean score for the class (we could retrieve 62 student models) was 13.75 (stdev = 2.42), which we will use as reference during the case studies. Spearman's Rho Correlation analysis indicated a moderate but significant correlation between the pictorial representation and Rule-based conceptual model scores (r = 0.35, p = 0.0007, n = 90), but a small non-significant correlation between Rule-based model and Computational Model scores (r = 0.19, p = 0.13, n = 62), implying the relation may not be linear. We observed that 68% of the students had correctly working computational models and 92% implemented the three conditions correctly. These results suggest that students' understanding of the runoff system improved upon constructing their computational models (though some students received help from the teachers or the researchers when constructing their models). For a deeper evaluation of students' modeling processes over time, we present contrasting vignettes for three students. Each student's final computational model is shown in Figure 3.



(c)

Figure 3. Final code for Alex (a), Marley (b), and Taylor (c).

Student 1: Strongly integrated science and CT

We selected Alex (name altered) for their strong performance on the pre-post assessment and curricular activities. On the pre-post assessment, Alex's score improved from 17.5 to 20 on the science and engineering assessment and from 10 to 13 and on the CT assessment.

During the conceptual modeling task, Alex correctly modeled each rule and demonstrated mechanistic understanding of conservation of matter. In response to the prompt to model water flow for 3 inches of rainfall and a 1inch absorption limit, Alex wrote: "*1 inch of that gets absorbed into the ground and since that's the absorption limit, the rest of the two inches becomes runoff*." This response indicated that Alex correctly calculated the runoff and total absorption based on the absorption limit and total rainfall and correctly described the process and mechanistic causal relations.

Alex's conservation of matter knowledge transferred to the Rule Creation task, where they could correctly define each rule (both the conditions and the output) via descriptive written responses. For example, in describing the "greater than" rule, Alex wrote: "*If the total rainfall is greater than absorption limit, set absorption to absorption limit, set total runoff to total rainfall⊠absorption*." This also translated to their building the correct computational model for a score of 15 out of 15. As shown in Figure 3(a), Alex correctly built each condition (lines 4, 7 and 10) and set each variable in the correct location and in a generalizable form (e.g., for the greater than condition (lines 4-6), the student calculated total runoff using the subtraction operator and used the variables total rainfall and total absorption, after setting total absorption to the absorption limit). Using our conceptual framework (Figure 1), Alex's learning trajectory is illustrated in Figure 4.

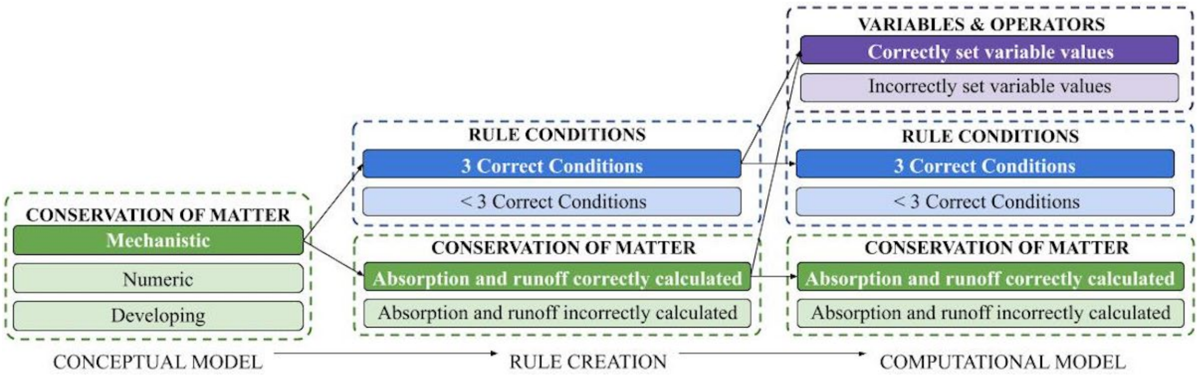


Figure 4. Alex's learning trajectory.

Student 2: Conservation of matter difficulties, high CT proficiency

Marley demonstrated pre-post CT learning gains (improving from a score of 6 to 8), but Marley's science and engineering scores decreased from pre-to-post (from 14 to 11). These results are consistent with Marley's trajectory from conceptual to computational model as described below.

Marley appeared to have difficulties implementing the conservation relation during the conceptual modeling task. For instance, when illustrating what happens when rainfall is less than the absorption limit, Marley indicated an absorption total greater than the total rainfall and stated "*it absorbs more rainfall than actual rain*" indicating a potential confusion about total absorption and absorption limit. During the Rule Creation task, Marley showed knowledge of conditional logic, providing a written response addressing each condition (e.g., "*If total rain = absorption [limit]*"); however, they did not correctly define the outputs for each rule indicating they did not fully understand the conservation law. Marley's ability to apply conditional logic translated to the computational modeling task. Their final computational model (Figure 3b) shows that Marley eventually built correct conditional blocks for two rules (lines 4-6 and 7-9), but struggled with the condition where rainfall exceeds the absorption limit (lines 10-12), thus receiving a score of 12 out of 15.

These results indicate that Marley leveraged conditional logic understanding to support the translation of the conservation of matter concepts into computational form (e.g., decomposing the code into conditional parts and then constructing blocks needed for each output). However, difficulties in the science domain may have limited their ability to correctly build and debug the model. Marley's learning trajectory is illustrated in Figure 5. While they demonstrated CT proficiency, the persistence of their struggles with the conservation law affected their ability to construct the correct computational model.

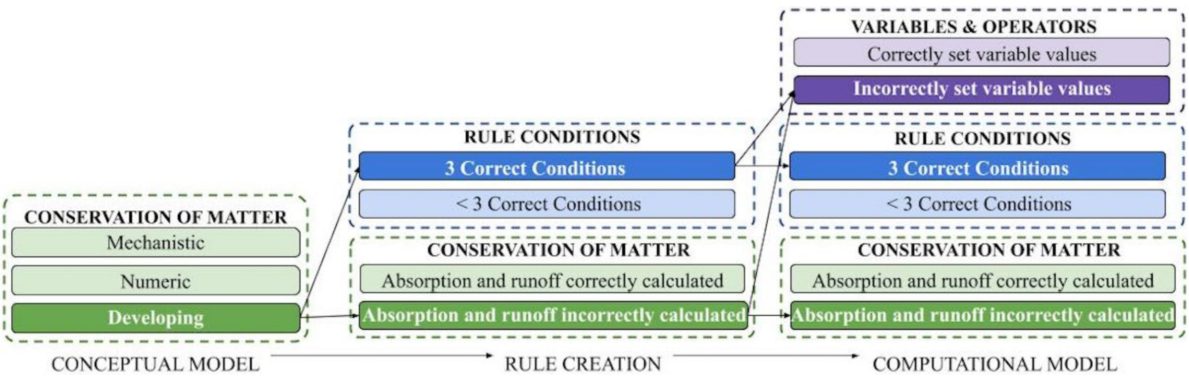

Figure 5. Marley's learning trajectory.

Student 3: Conservation of matter progress, but difficulties with CT integration

Taylor earned a relatively low score on the pre-assessment, but did achieve pre-post gains in both science and engineering (improving from 11.5 to 14.5) and CT (improving from 5 to 8). During the conceptual modeling task, Taylor demonstrated a numerical understanding of the conservation of matter rules. Taylor correctly determined the total absorption and calculated the runoff based on a prompt of a total rainfall of 3 inches and an absorption limit of 1 inch. In their description, Taylor wrote "*the cloud rained 3 inches and the ground absorbed 1 and others become runoff.*" This description does indeed include all needed variables, but does not describe the mechanistic reasoning behind why or how to calculate the runoff. However, for the Rules Creation task, Taylor was able to correctly define each rule condition and successfully calculate absorption and runoff for each rule, demonstrating an improved ability to apply the central matter conservation relationship.

The computational modeling task appeared to be difficult for Taylor. Although the science task indicated their ability to correctly apply domain knowledge, Taylor had difficulties translating that knowledge to a computational form. As illustrated in Figure 3(c), Taylor tried multiple arrangements of conditional blocks, including an if-block in which the expression was set to a "*total absorption* ⌧*total rainfall*" expression (line 7) inside of the if-block for the greater than condition (line 6). Taylor's computational model received a score of 5 out of 15. these code snippets indicate that Taylor understood how to create if-blocks for each rule condition (e.g., total rainfall is greater than absorption limit); however, they seemed unable to translate their domain knowledge to correctly assign variables (e.g., total runoff), debug, or correct their code.

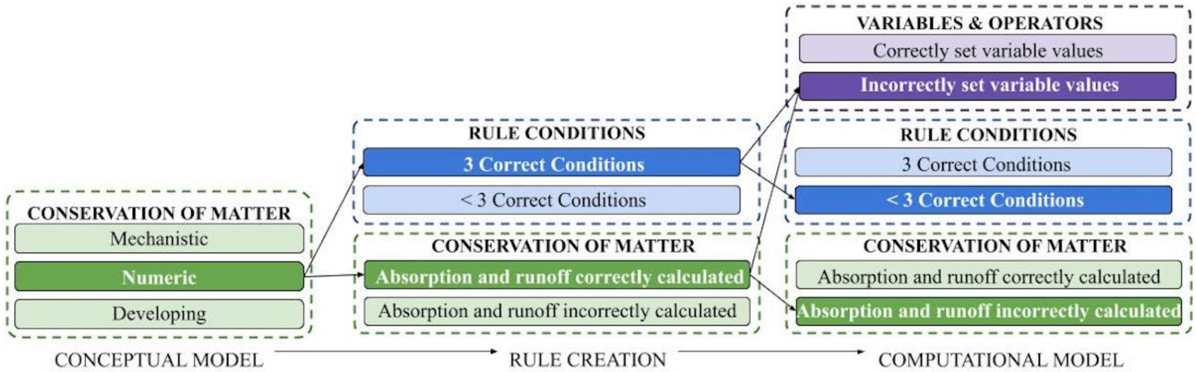

Figure 6. Taylor's learning trajectory.

Interestingly, after being shown the expert computational model and completing the remainder of the tasks, Taylor demonstrated learning gains in both the science and engineering and CT components, illustrating the potential for computational science modeling to help contextualize difficult CT concepts (e.g., conditional logic). Although they were not able to achieve a working computational model on their own, Taylor's successes in prior domain-knowledge application and usage of the model to problem-solve suggest improvements in their CT knowledge and skill. Taylor's final learning trajectory is shown in Figure 6.

Discussion and future implications

The overarching goal of our analysis is to develop linked model representations to scaffold students' computational models in science and understand how students transition across model representations to identify situations where they may have difficulties. This is especially critical in the context of integrated science and CT instruction and serves to disentangle the contributions of each domain and determine how students apply science and CT knowledge across model representations. Leveraging our conceptual framework (Figure 1), our analysis examines the impact of science domain knowledge on CT applications (and vice versa). Overall results showed that while there was a strong correlation between the conceptual model and the rule-based model, there was not a strong correlation between the rule-based model and the computational model, indicating additional personalized support may be needed for the more complex computational modeling task. For instance, although Marley was unable to correctly apply the conservation of matter rules during the conceptual modeling and rule creation tasks, their CT abilities guided them to an almost complete computational model and a high CT posttest score. Alternatively, Taylor indicated improvements in science, but demonstrated difficulties in translating that knowledge to a computational form. In these cases, using the curriculum design and student performance, we can identify the science and CT specific supports needed by the student in the computational modeling environment, and help students develop successful learning-by-modeling trajectories. In addition, these results align with other research findings that CT can serve as a vehicle for learning STEM concepts, but limitations in domain understanding may also impede computational model construction (cf. Sengupta et al., 2013). In terms of curriculum design, the majority of students indicated some proficiency in developing if-blocks in the computational model corresponding to the rules created in the Rules task. We believe this finding highlights a successful implementation of our coherence principle to support the transition from conceptual to computational modeling.

As schools move toward increased integration of computation in K-12 STEM classrooms, the learning sciences community must advance its understanding of the learning processes and support needs of students. Our analysis provides an exploratory step in identifying such cases, deepening understanding of how students integrate domain and CT knowledge for the development of multiple modeling representations. The identification of domain-specific instances of support along the learning trajectory may be supportive of more personalized (individual or group) feedback by the system or teacher. In addition, to promote student learning, our curriculum design approach and the coherence among modeling representations provide a systematic framework for evaluating applications of science and CT concepts over time. We believe this approach can inform curriculum design and scaffolding approaches that deepen understanding of how the domains are integrated, how students translate that knowledge to new representations, and where students may need additional support. Further research in applying our approach to other domains may support generalizability.

Abstract: Sweeping pandemic-driven school closures led to an unprecedented need for parents to become active participants in their children's day-to-day schooling. In this paper we report findings of a remote diary study that captured 109 diverse families' experiences during the first wave of U.S. closures with the goal of understanding the ways in which families were adapting to remote learning. We address three main questions: (1) What learning partner roles did parents assume when schools transitioned to remote teaching and did they vary by family income level?; (2) How did these learning arrangements help families address the unique challenges they faced? and (3) Were there unexpected benefits? Our findings show how parents took on new roles by listening in on instruction, supervising learning, providing technical support, brokering connections, and collaborating. Benefits included new insights about what and how their children were learning.

Key terms: COVID-19, remote methods, families, diary studies, learning partners

Introduction

The pandemic-driven school closures have dramatically blurred the boundaries between homes and classrooms. Although buildings were shuttered, most districts expected school to continue during the academic year and provided varied sources of support for academic learning and school community during this time. Parents and other adult caregivers at home took on new roles as facilitators of remote learning as they simultaneously adapted to new arrangements for work and strategized to protect their families' health and wellbeing. Experiences differed dramatically with more challenges faced by families who had fewer financial resources, lacked broadband access, and or had greater demands for work outside of the home (Pew Research Center, 2020). What we know less about is *how* families reorganized to capitalize on what schools were able to provide as well as their own resources.

In order to advance our capacity to support remote learning in the future, we need to understand how parent and child interests and funds of knowledge serve as assets and sources of resilience during the adaptation to remote learning, as well as how interruptions to work and school routines may disrupt the capacity to leverage them. The unique configurations of demands on families and the resources schools were able to provide, make it evident that adaptation processes and outcomes will be highly situated. If we are to understand and define resilience-building practices in ways that can set the stage for innovation, theoretically and methodologically varied approaches will be needed to surface learning practices that emerge within particular family-school ensembles and capture trends across families.

In this paper we report select findings from a remote diary study that captured a diverse set of families' experiences during the first wave of U.S. school closures in the Spring of 2020 with the goal of understanding the impact of the Covid-19 pandemic on family life and the ways in which families were adapting to remote learning. We consider the questions: (1) What learning partner roles did parents take on when schools transitioned to remote teaching and did they vary by family income level? (2) How did these learning arrangements manifest for particular families to address the unique challenges they faced? and (3) Were there unexpected benefits? To answer these questions, we analyze responses from parents and other adult caregivers to a series of daily prompts about remote learning at home over the course of approximately two weeks. We present quantitative and qualitative summaries of the types of learning support roles and benefits that were identified across all participants and share two family case portraits that showcase how adults at home supported engagement and learning by extending school assignments, brokering access to resources, and creating and collaborating on projects.

Theoretical background

To frame our inquiry, we draw on ecological and sociocultural perspectives of development. This view foregrounds learning as a cultural process that builds on prior practices and routines but that is characterized by innovation as tools and needs change (Marin & Bang, 2018; Moll et al., 1992). Learning is recognized as deeply social, facilitated by joint attention and mutual engagement with multiple roles for both guides and learners. Finally, learning is viewed as distributed and influenced by activities and resources provided across settings (Nasir et al., 2020). This ecological and sociocultural framing leads to an analytic focus on the ways that both children and caregivers dynamically shape learning activities and social interactions, including ways that learning occurs through "intent participation" (p. 176) by observing and listening in on ongoing activities (Rogoff, 2003). Parents' funds of knowledge, grounded in their own expertise and valued activities, help to shape activities as do children's interests and preferences. Ethnographic studies of family learning find that routine activities such as cooking, going on family outings, and connecting to nature provide opportunities to engage in math and science, even though many learners might not connect these to academic domains (Goldman & Booker, 2009; Zimmerman & Bell, 2014). The expression of parents' funds of knowledge is particularly important to understand now as they take on new roles in supporting their child's social, emotional and academic learning and as they develop novel insights through the process. Accordingly, we focus on how caregivers worked to coordinate, tailor and extend opportunities during this time and begin to describe some of the benefits that resulted. We build on prior research that identified unique parent roles as brokers, collaborators, and guides through varied forms of joint media engagement (Barron et al., 2009; Takeuchi & Stevens, 2010).

Methods

Ethnographic research with families has been a key feature of the literature on family learning and parent roles in supporting children's learning. However, Covid-19 challenged the field to quickly respond at scale to understand the changes that families were experiencing within the constraints of public health orders. In order to document the impact of the pandemic on families as it unfolded, our team chose to conduct a remote diary study with a socioeconomically diverse sample of families around the U.S. Diary studies are a form of experience sampling (Csikszentmihalyi & Larson, 1984) that allows researchers to systematically collect participant reflections on moments in their lives as those moments occur. In previous work, our team tested the method employed in this study for investigating how digital resources are used for learning at home (Barron et al., 2020) and demonstrated its utility for documenting learning moments happening in homes around the country.

Starting in May of 2020, several weeks after schools began closing, we collected daily documentation from 109 families across the U.S., with children aged 5-10 using dscout, a smartphone-based remote qualitative research platform. dscout maintains a panel of over 100,000 participants around the U.S. who are roughly representative of the smartphone owning population. dscout allowed our research team to interact with families and collect rich qualitative data without face-to-face contact, affording broader geographic reach and pandemic-safe practices. The approach also has affordances for participants, including freedom of movement while working through parts of the study and uploading videos and pictures in real time. The ease of submission ensures greater accessibility; a busy parent, for example, can snap a quick picture of their child doing an activity and upload it while also making dinner. Videos taken at home with background noise from children and pets provide rich context previously reserved for expensive and potentially intrusive home visits.

A total of 1,375 people from dscout's participant panel expressed interest in participating by completing an initial screener questionnaire, which included IRB consent to participate in research; 264 respondents fit our study criteria: (a) having a child between ages of 5-10 living at home, (b) the child's school had moved to remote instruction and was in session for the entire duration of the study, and (c) the applicant had given consent for their responses to be used for research. These 264 applicants were sorted into three household income groups: \$0-49K (15%), \$50-99K (44%), \$100K+ (41%). Thirty-seven initial participants were randomly selected from each group. In total, 109 participants from 28 states completed the study. Most (67%) were female and 55% self-identified as white, 16% as Black, and 15% as Latinx, 9% as Asian, and 4% as Middle Eastern or North African. While most participants were parents, some were other adult caregivers in the homes of children (for example, adult siblings, grandparents, live-in partners of a biological parent).

Data collection was organized in five parts that participants completed over the course of two weeks (Table 1); each part included multiple-choice survey items, open-ended text responses, image uploads, and video prompts. Part 3 (learning diary entries) asked participants to capture one learning moment per day for six days. Participants submitted 668 diary entries that each focused on a single learning moment. Our team used a mixed-methods approach to explore the data, including descriptive quantitative summaries; coding open-ended text responses and video transcripts across cases to capture variation in themes using inductive and deductive approaches (Saldaña, 2013); and developing case portraits to help theorize parent-identified examples of learning collected in the diary entries.

Table 1. Data collection components organized in dscout

Component	Topics covered
Application	Demographics; school closing status; remote learning challenges; IRB consent for research
Part 1	Pre-pandemic home and school academic access and support
Part 2	During-pandemic learning resources provided by schools; how parents were supplementing and supporting learning (based on earlier work on parent learning partner roles, Barron et al., 2009)
Part 3	Six unique entries (one per day), each including: photo and verbal description of a learning moment; identification of activity origin and content; ratings of enjoyment and learning
Part 4	How families were learning about Covid-19; examples of questions children were asking and reflection about a conversation they had with their child about the pandemic
Part 5	Reflection on possible benefits of remote learning and insights about what and how their child learned; evaluation of how well child kept up and how caregivers adapted to remote learning

Findings

RQ1: What learning partner roles did parents take on during remote learning?

Participants were asked to indicate if they had "arranged any learning situations for their child while they were out of school due to the pandemic," from a list of items (Table 2) adapted from earlier work (Barron et al, 2009). The majority of parents collaborated with their children on projects and brokered new learning opportunities for them by seeking out online activities. Although many considered themselves to be playing the role of a direct teacher, over a third also reported learning from their child as they navigated learning at home together.

Table 2. Parent learning partner roles

	N participants	%
Collaborating and co-learning		
Collaborated on projects with my child	65	59.6%
Learned something from my child	42	38.5%
Guiding academic work		
Acted as a classroom teacher	50	45.9%
Acted as a project manager to help them manage time/work	32	29.4%
Providing resources		
Used reading materials I had around to support my child's learning	49	45.0%
Bought my child extra books, videos, computing devices to supplement	43	39.4%
Brokering opportunities		
Looked for activities my child can do online	68	62.4%
Signed my child up for an online educational program/website	28	25.7%
Coordinating connections to learning partners		
Asked a family member or friend to help/tutor my child online	10	9.2%
Hired an online educator for other subject areas (music, art, other)	3	2.8%

We compared learning partner responses from three household income groups (lower = \$0-49K, middle = \$50-99K, and higher = \$100K+). Parents and other caregivers reported an average of 4.7 learning partner roles (SE = 0.245) reflecting the diversity and breadth of ways that they were supporting learning. This was not significantly different across home income groups suggesting that despite differences in financial resources all caregivers were finding ways to enhance learning opportunities, complementing what teachers could provide.

Qualitative descriptions of the learning moments shared in the daily diary entries through video reflections allowed us to broaden our understanding of the ways in which caregivers were playing the roles they selected in the checklist. For this paper, we share five roles evident in the ways parents supported their children's learning while school buildings were closed. *Collaborating*, *guiding work*, and *brokering opportunities* are examples of roles apparent in earlier research (Barron et al., 2009) but manifested in slightly different ways during remote learning. *Listening in* and *providing technical assistance* are examples of distinct roles that emerged from this data. Examples are drawn from transcripts of caregiver provided diary entry video submissions describing the learning activity, what was being learned, and who was involved.

Collaborating

Some diary entries described caregivers working and learning together with the child. These collaborative moments spanned different activity types, including family-initiated projects, classroom-generated work, deep learning discussions, and reading a novel together. Importantly, in these moments identified as collaborating, both parents and children are engaged in a shared learning experience as opposed to a child asking for help or a parent instructing them. One example is Lucy's description of a generative open-ended science discussion with her kids that unfolded over the course of an outside walk.

> ...we went on a puddle walk and we talked about all the different things we saw. We talked about things that floated in the water, the different worms that were coming up. …one of those unexpected learning moments where we got to incorporate the fun things and activities and going out into the world and getting some exercise with some learning and talking about just nature and how water- we talked about the water cycle and where rain comes from and what all the clouds were up there for and all those sorts of things while on our puddle walk. (Lucy G)

Guiding academic work

Caregivers often talked about moments during which they were helping their children with schoolwork. Sometimes they directly taught required concepts and skills, while other times they operated in a more supervisory capacity. As supervisors, they helped read and interpret assignment instructions, double-checked their child's work, and helped with time and task management, including ensuring that assignments were completed and online classes were actively attended. For example, Agnes was at the ready to ensure that her Kindergarten daughter was successful achieving the day's academic expectations:

> ...this packet was the math packet and she was doing the tens and ones learning that and actually she knows it pretty well so there was very very little that I need to do. But I was there just in case she did have any questions and then also [to] check her work to make sure that she did it correctly... (Agnes W)

Brokering opportunities

Caregivers frequently play key roles in enabling their child to access learning experiences, such as signing them up for science camp. During remote learning, these brokering moments were identified at a more immediate scale. Caregivers connected their child to activities or learning resources from day to day, based on their child's expressed or observed interests and also specifically to extend or supplement learning activities that originated from school. In this example, Pranav noticed a particularly fun engineering activity her Kindergarten son did during virtual class and encouraged him to continue it in different directions after the class was over.

> So, the teacher gave them the activity, so my kid was creating that cube [using sticks and marshmallows] and, and other kids were creating the cube as well on the Zoom. ... And he really enjoyed this activity and competing with his friends on Zoom, and he was proud to show his teacher. … And we made him, you know, make some other shapes as well after the class, little rectangles and triangles. (Pranav R)

Providing technical assistance

In talking through a learning activity, caregivers sometimes described how they helped with technology requirements. One way was to troubleshoot technology issues as they came up for the child (e.g., resetting routers to address connectivity issues, finding passwords to log their child into an online learning platform, and tracking assignments on learning management systems). This role also covered parents designing technical workflows to enable the submission of assignments or the coordination of novel technology scenarios to support learning. For example, Arielle reported needing to facilitate her fourth-grade daughter's access to assignments:

> The other challenging part is the fact that a lot of the teachers did not send home their textbooks. So, everything is being scanned and given to them through Google Classroom. So that's been

> another problem and what we've been doing is printing them out for them and then I just re-scanned them into the computer to email them to their teachers. (Arielle K)

Listening in

During moments identified as listening in, the caregivers actively observed their child participating in a virtual class or meeting, often listening in from a distance. This type of activity is a common form of human learning in informal settings (Rogoff, 2003). Moments of listening in on virtual instruction were frequently paired with reflections about teacher-child interactions and child engagement, which sometimes prompted associated ideas for further support. For example, through listening in and observing a classroom session over Zoom, Cara admired the teacher's use of familiar tangible referents to teach fractions, particularly noting her daughters' focus, enjoyment, and understanding of the content. This gave Cara new ideas, and in her following diary entry, she extended a play activity with her first-grade daughter to partition shapes using Play-doh.

> And her teacher was really doing a good job in explaining to them how fractions and partition works by showing just practical examples and practical objects like, a piece of cake or a piece of pizza. So the kids will understand it very easily and without complication. ... I really thought that this session was so meaningful knowing my daughter's least favorite subject is Math, she looks so focused and was having fun. It gives me ideas too of how to deal with her when it comes to teaching Math. (Cara P)

RQ2: How did learning arrangements manifest for particular families?

While the quantitative indicators show that all families, regardless of income, took on a breadth of new roles as learning partners during this time of remote instruction due to Covid-19, the integrated case portraits summarize learning across diary entries and illustrate in more depth *how* they sustained their child's engagement in learning. They also contextualize the unique situations they faced and begin to help us understand how new roles and new views led to new insights and ideas. The following two cases differ in the age of their focal child (at the older and younger spectrums of our age range) and household income (higher and lower) but both reveal unique strategies, challenges, and benefits in their stories of learning moments. Table 3 shows a summary of participant-reported data for the two caregiver cases and narrative portraits follow.

Table 3. Summaries of demographic data and responses to roles and benefits as reported by case participants

Participant	Jade	Astrid
Relationship to child	Grandmother	Mother
Child gender, grade, age	5th grade male (11 years old)	Kindergarten male (6 years old)
Home income	Lower (25-49K)	Higher (125-149K)
Highest education level	High school	Post graduate work
Employment status	Part time cashier	Full time work in field of education
Roles identified in the questionnaire (Table 2)	Provided reading materials in the house Purchased new learning materials Found online learning opportunities Collaborated with child Signed child up for online program	Provided reading materials in the house Purchased new learning materials Found online learning opportunities Collaborated with child Learned something from child Acted as a project manager

Jade and Henry: Crafting projects, providing materials, and collaborating to learn

Jade was her fifth-grade grandson Henry's primary caregiver and was deeply involved with his learning during the pandemic. Henry has a documented learning disability and receives extra support from a resource teacher, but Jade's advocacy was important for helping him continue to progress during distance learning. At the start of the pandemic, the school worked to get connected remotely but were slow to provide clear plans and learning objectives that would meet Henry's needs. In response, Jade *listened in* on Henry's classes, occasionally stepping in to *supervise* and *broker activities* as needed to make sure that he had appropriate assignments and support. For instance, in math class Jade noticed that the concepts the teacher was covering were more advanced than the content Henry was working on, and she supported him to leave the meeting and work on math using Zearn or listen to a book from Epic's digital library. Listening in on virtual classes also gave Jade a view into challenges with peer interaction. On one occasion Jade noticed that he was being excluded during a group project, so she intervened with the teacher to allow Henry to work on his own. Connecting with Henry's resource teacher proved to be a recurring struggle because of the teacher's inconsistent Wi-Fi connection and schedule, forcing Jade to become a *technical assistant* for Henry as she monitored her phone for updated schedules and Zoom links. In addition to advocating for Henry's needs and adapting instruction in the moment, Jade *collaborated* with Henry on assignments, such as making a video of them cooking dinner for an assignment, and extending his learning through projects and connecting him to resources. She noticed Henry's interest in a historical fiction show, PBS' "Liberty Kids," originally assigned by his teacher, found the whole series on Hulu, and let Henry watch it in the morning while he played with Legos to improve his hand-eye coordination. For fun, Jade taught Henry how to sprout a carrot from a top, supporting conversations about how roots grow, photosynthesis and how to observe changes over time. Henry was able to share this project with his classmates during an online show and tell session.

Overall, distance learning proved both challenging and rewarding for Jade and Henry. Although Jade frequently expressed frustration in her entries about a range of struggles related to advocating for Henry's needs, she and Henry were able to share moments of excitement and have fun learning together. Having access to personalized instruction platforms enabled Jade to supplement Henry's learning, and she believed that these systems directly led to her grandson's reading and math levels moving forward one year. Additionally, by listening in to Henry's online sessions and observing how well he did when working at his own pace, she developed a more nuanced understanding of his strengths and challenges. In her final reflection she shared her plans to "work hard and be diligent on knowing exactly what he is studying in school to move him forward when he needs to be moved forward," articulating the value of her new role as a learning partner and advocate both in the current moment and in the future.

Astrid and Arlo: Leveraging technology to connect with family and support collaboration

Astrid was minimally involved with her kindergarten son Arlo's schoolwork. Arlo was already reading at a first-grade level and was bored by math worksheets that were too easy for him, which made it hard for Astrid and her husband to keep Arlo engaged with assignments. *Listening in* on class and *supervising* Arlo's work gave Astrid a new perspective on his behavior in class. She reflected, "I understand more why he might talk so much in class… he's bored!! I didn't really know…" Outside of class, Astrid noticed and documented more independent learning—Arlo is an avid reader, which Astrid described in an entry she submitted showing a picture of Arlo sitting in bed with his tablet. She explained that Epic was "like going to a library" for Arlo and that she "got an email from the app that said that he read 17 books yesterday [...] everything from UFOs to some stories about bears." Arlo's access to Epic was going to continue through the summer and Astrid planned to continue encouraging Arlo's use of the app because she saw how easy it was for Arlo to choose books that interested him and further his reading skills. In her final reflection Astrid noted that she and her husband were typically not involved in Arlo's schoolwork and that she appreciated this opportunity to be more involved in his learning. Despite the frustrations of too many apps, too many scheduling challenges, and too much to manage, she valued her new insights about his need to be challenged, made possible by the unique opportunity to sit in during online class sessions.

Overall, Astrid was more concerned about Arlo's social and emotional well-being than his academics. Daily Zoom classes offered some social interaction, but because Arlo was an only child, he and his parents created other opportunities to connect with family remotely and share learning experiences. Video chat access enabled Arlo to read to his three-year old twin cousins and collaborate with his grandfather on a STEM learning project. Astrid *brokered these activities* by being a *technical assistant* and resource provider. It was Arlo's idea to read to his cousins, and he modeled his reading performances for them based on Story Time Online, a site where famous authors read books aloud, reading the text and then showing the pictures in the book to his cousins. Arlo also chose the activity that he wanted to do with his grandfather, creating a balance scale, and Astrid assisted with the digital workflow by taking pictures of the pages of the book and sending them to her father ahead of time. Astrid and her husband were working while Arlo was online with his grandfather, *listening in* but otherwise not involved. She described how, "my kid led the process. My dad followed along and then once they built the scale they measured a bunch of different stuff [...] It was really neat actually just [to] see them working together and it was [...] something that we really hope that we can try to do again."

RQ3: Were there unexpected benefits?

Encouragingly, there were a number of benefits participants reported from partnering with their child during remote learning, including new knowledge and social learning networks (Table 4). Over three quarters of caregivers appreciated the unique opportunity to know more about their child's learning and over one third felt more connected to their child's academic environment, regardless of income.

Table 4. Reported beneficial situations related to teaching and learning at home

	N	%
I am more aware of what and how my child is learning than usual	84	77.8%
I am more connected with my child's school/teacher than usual	44	40.7%
Child teaches other family members	22	20.4%
Relatives and/or family friends are helping my child learn	17	15.7%

On the checklist, both Jade and Astrid reported being more aware of their child's learning, and Astrid additionally reported being more connected to Arlo's school/teacher and that other relatives were involved in his learning. The intersection of parent roles and perceived benefits is clear in both case portraits. Jade listening in on her grandson's class work prepared her to advocate for modifications to better fit his learning style. Her communication with the teacher shifted instructional strategies. Through the unique vantage point of listening in, Astrid gained insights about her son's need for more challenging activities which encouraged the family to embrace personalized content selection through digital libraries. Her coordination of new opportunities for her son connected him to bidirectional learning and collaboration with his grandfather and younger cousins.

Discussion

Our intent was to understand how an economically diverse set of families adapted to the first wave of school closures, the troubles they encountered, and the solutions they generated in real time. In the analyses reported in this paper, we found that caregivers across income groups supported distance learning by collaborating, guiding academic lessons, brokering access to additional resources and coordinating connections to additional partners. We also found parents taking on both new roles and existing roles with variations.

As exemplified in the case portraits, we found that when parents took on responsibilities as co-teachers, collaborators, brokers, and coordinators, they had novel opportunities to observe their child as a learner, expanding their opportunities to informally assess their child's social, emotional, and academic needs and in response design learning arrangements that addressed them. The learning diary data analyses also point to ways that access to technology is only part of ensuring equity of learning opportunities online; unequal access to synchronous classroom experiences may introduce new learning opportunity gaps (Pozos, et al. 2021). For example, when caregivers were able to listen in on synchronous lessons held on video conferences, they generated new insights about what was working for their child or not. These views offered the occasion to draw on teachers' practices to design and tailor their own learning arrangements or to craft alternative learning opportunities to make up for the challenges presented by remote teaching. Listening in during synchronous sessions also allowed caregivers a chance to notice social and emotional aspects of learning remotely, including children's strategies to make themselves comfortable, challenges and benefits of peer interactions, and struggles to focus and pay attention. In the short term, these insights were used to tailor learning activities. In the longer term, some caregivers were positioned to serve as more knowledgeable advocates for their child, a benefit that could lead to consequential outcomes over extended learning pathways (Nasir et al., 2020). Caregivers' experience with technology may also contribute advantages. For example, taking on responsibility as a technical assistant may be easier for those parents who are more fluent with technology (such as those who are themselves using Zoom for their work meetings) and have access to experience with various devices and the devices themselves. These examples of the intertwining of the technical and social aspects of remote learning are consistent with evolving conceptualizations of digital divides as multidimensional, overlapping, and intersectional (Van Deursen & Van Dijk, 2019).

Future directions

As researchers, caregivers, and educators move forward to improve remote learning, novel forms of collaboration and interdisciplinary approaches to knowledge creation will be needed that address the social and technical aspects of equitable learning. Our preliminary findings suggest several directions for use-inspired design and research to help meet the needs of children, caregivers, and the educators who serve them. In particular, these findings reflect the potential for design-based research to identify ways to catalyze new forms of parent/teacher collaboration organized to share insights about learning. Although unintentional, some teachers are implicitly providing caregivers with opportunities to learn about their child as a learner and about their classroom experiences. This insight might be leveraged in future designs that aim to strengthen the distributed teacher-family learning team. It is also clear that teachers have much to learn from the educators at home. Caregiver observations documented in the diary entries showed that they were attending to their child's feelings, their interests, and their understanding of content, providing crucial formative assessment data that most teachers are currently lacking and missing terribly (Darling-Hammond et al., 2020; Reich et al., 2020). The affective dimensions of learning moments are greatly in need of attention, and future work may productively focus on the practices and collaborative conditions that support resiliency as reflected by closer caregiver-teacher communication and mutual support of learners' interest, curiosity, joy and sustained engagement.

Challenges in Interpreting Student Responses for Three-Dimensional Classroom Assessment

Clarissa Deverel-Rico, Erin Marie Furtak
clarissa.deverelrico@colorado.edu, erin.furtak@colorado.edu
University of Colorado Boulder

Abstract: Recent reforms in science education have emphasized the importance of students engaging in three-dimensional learning consisting of science practices, disciplinary core ideas, and crosscutting concepts. However, this kind of learning is challenging to assess, and necessitates multicomponent tasks that allow multiple opportunities for students to share their developing understandings. This paper explores the complexities that arise in interpreting student responses and planning for next instructional steps through the analysis of a three-dimensional, phenomenon-based task for high school students' modeling of cellular respiration. We describe two approaches for looking at student responses, and analyze the affordances and constraints of each method. We conclude by discussing practical considerations for classroom teachers and implications for developing three-dimensional classroom assessments.

Introduction

Science education has been undergoing a major wave of reform in the past decade. Building on shifts in situated and sociocultural theory that frame learning as changes in participation in disciplinary practices over time (e.g. Wenger, 1998), these reforms prioritize students' engagement in what has been called three-dimensional science learning (National Research Council [NRC], 2012). This kind of learning involves students participating in science and engineering practices to learn disciplinary core ideas and apply crosscutting concepts as they seek to explain everyday, observable phenomena around them (National Academies of Science, Engineering and Medicine [NASEM], 2019).

This new vision of science learning has placed great demands on classroom assessments that can capture the complexity of student engagement in disciplinary practice. While the field is developing new approaches to designs for assessment tasks, teachers, assessment and curriculum developers are still determining the kinds of tasks that can truly draw out all three dimensions of students' experiences. At the same time, once students have responded to these tasks, teachers are left to interpret student responses to determine next steps for instruction. This presents a heavy lift for teachers still working to understand the three-dimensional vision themselves.

In this paper, we take the example of a co-designed, three-dimensional formative assessment task for high school biology to examine the complexities revealed when interpreting student responses that combine science practices, disciplinary core ideas, and crosscutting concepts. We examine student responses by disaggregating the three dimensions, as well as holistically, determining similarities and differences that could be consequential to teachers' interpretations and determinations of next steps for instruction. We conclude by identifying design considerations for developing three-dimensional science assessments.

Formative assessment tasks as mediating artifacts

We view learning as changes in participation in disciplinary practices over time (Wenger, 1998). From this perspective, classroom assessment can be viewed as an activity in which teachers and students reflect upon how participation in practice is changing (e.g. Greeno & Gresalfi, 2009). This perspective on learning and assessment is starkly different from prior views of assessment as an activity that seeks to understand the 'knowledge in a learner's head,' framed from behaviorist and cognitive views of learning (Shepard, 2000). Further, we view assessment tasks as mediating artifacts that organize classroom activity (Wertsch, 1998). In the context of three-dimensional learning, where students' participation in disciplinary practice is being assessed, along with their understandings of disciplinary core ideas and application of crosscutting concepts, the tasks serve as material representations of student thinking (e.g. Cowie, Jones & Otrell-Cass, 2011) that teachers and students together reflect upon and respond to as they determine subsequent directions for learning.

Three-dimensional science learning

The new vision of science learning consists of three elements - science and engineering practices, disciplinary core ideas, and crosscutting concepts - in which students participate over time (NRC, 2012). This reconceptualization of science learning is built on the 'practice turn' in situated learning theory (Ford & Forman, 2006). Science and engineering practices are ways that scientists and engineers understand the world around them and design solutions to address problems (Schwarz, Passmore & Reiser, 2017). These practices include modeling, or creating simplified representations of phenomena that make its different elements explicit (e.g. Harrison & Treagust, 2000; Schwarz et al., 2009). Modeling has been called the central practice of three-dimensional learning, as it can be placed at the center of other practices such as asking questions, designing investigations, analyzing data, and developing explanations (Passmore, Schwarz, & Mankowski, 2017). Disciplinary core ideas are the second dimension of three-dimensional learning, and constitute the big ideas in life, physical, earth and space science. The third dimension, crosscutting concepts, are sometimes framed as the questions scientists ask themselves when they don't immediately know the explanation for an observable event (Furtak et al., 2021). Crosscutting concepts include systems and systems models, patterns, scale, and matter and energy cycling (NRC, 2012). The latter of these crosscutting concepts - energy and matter cycling - is unique as it is also a disciplinary core idea. For example, students may learn about the role of energy in force and motion in physics, and then relate energy to endo- and exothermic processes in chemical reactions before learning about energy transfer and transformations in photosynthesis and respiration in a biology course.

These three dimensions are designed to span grade bands and build in complexity as laid out in the Next Generation Science Standards (NGSS; NGSS Lead States, 2013). Accordingly, students' explanations of phenomena will deepen given these multiple opportunities to bridge everyday understandings with scientific principles and develop into describing causal relationships (Braaten & Windschitl, 2011).

Challenges in designing formative assessment tasks for three-dimensional learning

A central element to realizing the new vision of science learning is designing classroom assessment tasks that reinforce, rather than work at cross-purposes with, three-dimensional learning (NRC, 2012; 2014). Formative assessment tasks serve to surface what students know and can do so that teachers and students alike have information about the current learning goals. With this information, teachers can respond accordingly to leverage students' understandings towards meeting the objective. Three-dimensional formative assessment tasks use multiple components to elicit students' three-dimensional learning, and mediate classroom conversations that create space for students to share and respond to each other's developing ideas. In this way, three-dimensional formative assessment consists both of the tasks that teachers can use to draw out student thinking, and the practices that organize classroom activity around the sharing and working out of student ideas (Bennett, 2011).

Not all formative assessment tasks, however, draw out student ideas equally. Kang and colleagues (2014) found that some scaffolds can be more supportive of engaging students in developing an explanation for an observed phenomenon than others. In particular, contextualizing an assessment task with a phenomenon along with another scaffold supports student learning. For example, asking about forces in the context of a skateboarder rolling down a specific hill near the students' school provides an opportunity to apply developing ideas in an everyday and observable context. Then, scaffolding students' responses with sentence starters that help them identify causal relationships, or providing checklists that encourage them to provide specific elements in a model (e.g. to include both visible and invisible components), are more likely to help them share their thinking.

Formative assessment tasks can serve as the 'observation' of what students currently know and are able to do, and then teachers make inferences about the status of student learning to inform subsequent instructional experiences (e.g. NRC, 2001; 2014). The tasks can also serve as mediating artifacts around which other processes - such as whole-class discussions, or small-group conversations - allow students to share their ideas, and get feedback from their teacher and peers. Multicomponent tasks can be designed with this kind of feedback in mind so that students make initial and revised models and explanations, for example, with small-group and whole-class discussions in between. Then, through participating in these discussions, trying out ideas, and listening to their peers, students can integrate new ideas and representations into their models and explanations.

However, these kinds of task formats are still new, and the degree to which those tasks provide interpretable information for teachers is not entirely clear. The methods that teachers currently use for combing through student work to assess and/or identify next steps in instruction may no longer work for such complex three-dimensional tasks. For instance, sorting work into low, medium, and high categories will no longer be straightforward when a task is designed to capture multiple dimensions of learning, and if it contains initial and revised elements. If we are really trying to reconceptualize science learning, the NGSS forces us to rethink not just assessments, but also how to meaningfully interpret the learning demonstrated in such assessments.

In this paper, we seek to determine how we can score and evaluate student responses on these kinds of formative assessment tasks, and identify design considerations to facilitate more effective teacher use of formative assessment to support students' three-dimensional science learning.

Method

This paper analyzes data collected in a multi-year, research-practice partnership with high school science teachers in a large socioeconomically, linguistically, and ethnically diverse school district in the Western U.S. One of the goals of the partnership was to co-design formative assessment tasks around a modeling energy learning progression. In this paper, we focus on two biology teachers who co-designed a task around cellular respiration.

A learning progression for modeling energy

We founded our process of task design on a learning progression as a representation of the ways in which students might progress in their development of a disciplinary core idea or science practice (Corcoran, Mosher & Rogat, 2009). Learning progressions generally start with representing the experiences and preconceptions that students bring with them to school and progress with increasing sophistication of representing and interweaving ideas until reaching a level of mastery appropriate with grade level. We developed a three-dimensional learning progression for modeling energy transfers and transformations within the process of cellular respiration, including specific indicators or "look-fors" (Table 1). As this learning progression has served as a grounding framework for developing tools and routines in our work with supporting teachers to co-design 3-dimensional classroom assessments, it also serves as an analytical lens for evaluating what students know and can do from such tasks.

Table 1: Learning progression and sample DCI-specific look-fors (Buell et al., 2019)

Level	Description	Sample Look-Fors
5	• Students generalize their model to unknown or multiple phenomena and explain limitations of applying the model to a new phenomenon.	• [Task not designed for this level]
4	• Models illustrate a mechanism that can explain or predict the phenomenon, and make predictions about how changing one part of the model would influence energy flows elsewhere. • Students explain how the total energy of the system constrains the magnitude of change possible. • Students describe limitations of the model.	• Relationship between amount of inputs rate of cellular respiration; indicators of conservation and dissipation through different parts of the body; food molecules sustaining life processes
3	• Students' models relate changes in the phenomenon directly to changes in energy through transfers/ transformations by identifying specific, observable indicators. • Students begin to show evidence that their model is accounting for conservation and dissipation. • Model includes energy flows into, within, and out of the system.	• Relationship between amount of inputs and outputs in cellular respiration • Indicators of conservation and dissipation; eg. sweat, heat
2	• Students' models illustrate a relationship or pattern between the increase in one form of energy and the decrease in another form, or transferred from one location or object to another. • Students identify the most relevant components and relationships in the model and distinguish between the system and surroundings. • Model focuses on energy flows within the system only.	• Key inputs and outputs of cellular respiration (including oxygen, carbon dioxide); shows a flow of inputs in and outputs of cellular respiration
1	• Students use or develop a model that shows, through drawings or labels, the components involved in a phenomenon, some (but not necessarily all relevant) energy forms, transfers, or transformations.	• Components include food molecules or oxygen, but not a focus on how energy flows in cellular respiration

Data sources

We analyzed student responses to the respiration task co-designed with high school biology teachers and linked to the learning progression in Table 1. The task presents students with the phenomenon of how visiting athletes who play at elevation experience more fatigue than their 'home-team' counterparts, and was designed for use early in the unit about cellular respiration. The design of the task included multiple activity settings - individual work, as well as small group and whole-class discussions - intended to perform a learning function in which students surface their individual ideas, discuss them in multiple settings, and then create revised models. We analyzed 134 samples of student work collected from two biology teachers across six sections of their classes.

Each piece of student work consists of three subtasks: an initial model, three open-ended written-response questions, and a revised model.

Analytic approach

We developed a multifaceted coding system in order to capture the complexity of responses in students' initial and revised models, and in the explanations they provided on the basis of those models. The coding system allowed us to code each part separately (disaggregated approach, Table 2), and apply codes that looked at the whole task relative to the learning progression as an interpretive framework (holistic approach, Table 1). First, we segmented the student work into three subtasks (the initial model, the explanation, and the revised model). The disaggregated approach treated the initial model, explanation, and revised model as distinct entities. There are three codes for this approach: Phenomenon, Disciplinary Core Idea (DCI), and Type of Explanation. The Phenomenon code captured if students are writing or modeling their explanations in the context of the 'playing football at high elevation' phenomenon (Odden & Russ, 2019; Kang et al., 2014). The DCI code identified scientific content as related to the appropriate NGSS performance expectation (PE). Here, the PE (HS LS1-7) is centered around modeling matter and energy flows in the context of cellular respiration. The Type of Explanation code is meant to capture and identify the different approaches that can be taken in conceptualizing explanations of a phenomenon which might follow a "trajectory from describing 'what' happened to explaining 'how' and 'why' events happen" (Braaten & Windschitl, 2011, p. 663). We then interpreted the codes – which are organized hierarchically - as scores and created sum scores that aggregated student performance on the different categories.

Table 2: Codes for disaggregated approach to analyzing student work

Category	Code	Description
Phenomenon Student response links back to the phenomenon (Odden & Russ, 2019; Kang et al., 2014)	0	Does not refer to original phenomenon posed in task
	1	Refers to phenomenon
DCI (Disciplinary Core Idea) Identifies relevant macro and/or micro-level elements **of cellular respiration** (see Jin, Choi & Anderson, 2009)	0	DCI-related content not present
	1	Observable inputs and outputs, and ideas from everyday experiences
	2	Observable/experiential indicators with *some* identification of molecular inputs and outputs; Begins to connect macro and micro.
	3	Explanation describes *all* inputs and outputs including observable/experiential indicators
Types of Explanation This code indicates the kind of explanation students are using in order to explain the phenomenon (Braaten & Windschitl, 2011)	0	Explanation of phenomenon not present
	1	Everyday explanation
	2	Covering law - phenomena are the result of specific laws or law-like statements
	3	Emerging Causal - explicitly seeking underlying causes for events/phenomena
	4	Emerging Manipulationist - identifying mechanisms that answer how outcomes would change if the mechanism was manipulated or if there is a different desired outcome

Lastly, we used the modeling energy learning progression to holistically code the task as a whole. We drew upon the teacher-designed, performance expectation-specific "look fors" as indicators for holistically assigning the student work to a learning progression level. Although there are five levels to the learning progression, this classroom assessment task was situated at the beginning of an instructional unit and therefore not designed to attain a level 5. Three raters independently coded 20% samples of the student work, improving in Cohen's Kappa as an indicater of interrater agreement each round. Ultimately, given the high-inference nature of the coding approach, researchers adjudicated every piece of student work to reach 100% agreement.

Findings

Our analysis reveals differences, but also key overlaps, in the disaggregated and holistic coding approaches. We first present our findings from the disaggregated coding, and then look at broader themes from the holistic coding relative to the learning progression. Finally, we analyze the association between the two approaches.

Disaggregated approach

Table 3: Summary of Disaggregated and Holistic Coding Approaches

Code		Disaggregated Approach		
		Initial Model	Explanation	Revised Model
Phenomenon *Min=0, Max=1*	Mean	0.95	0.99	0.99
	SD	0.21	0.09	0.09
DCI *Min=0, Max=3*	Mean	1.19	1.31	1.40
	SD	0.80	0.55	0.84
Explanation Type *Min=0, Max=4*	Mean	1.18	2.00	1.37
	SD	0.81	1.02	0.81
		Holistic Approach		
Learning Progression *Min=1, Max=5*	Mean	1.52		
	SD	0.70		

Overall, the disaggregated approach revealed shifts between students' initial and revised models, as well as qualitative differences between student models and explanations (Table 3). The results of the Phenomenon code showed that in almost all instances (not including a small number of blank responses) students were modeling and explaining about the phenomenon. Across the initial model, explanation, and revised model, students referred to the phenomenon an average of 97.7% of the time. There were very few instances in which students provided an explanation devoid of context, which is in line with what we hope to see given the design of the task around a phenomenon.

The DCI and Explanation Type codes reveal differences across the subtasks. Across all student responses, we observed a shift towards more DCI understanding as students progress from the initial model (m = 1.19), to the written explanation (m = 1.31), to the revised model (m = 1.40). These shifts are visible in Figure 1, particularly in how more students reach a level 2 by the time they revise their model.

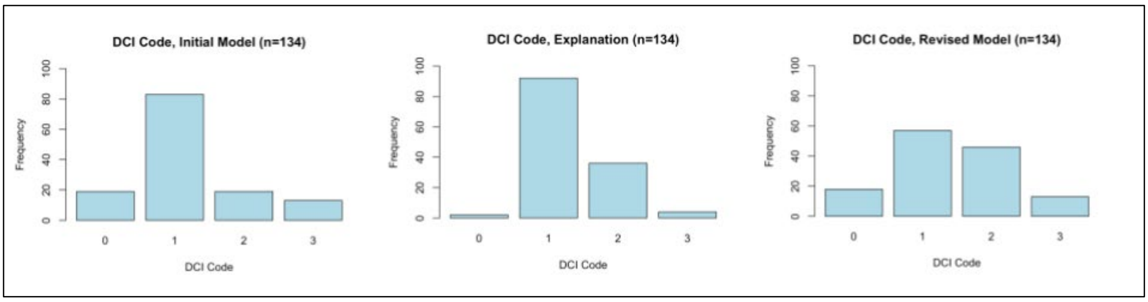

Figure 1. DCI code distribution across the three subtasks

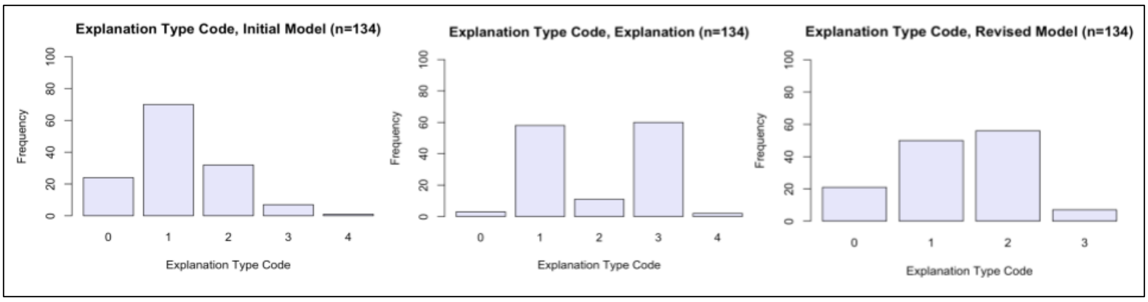

Figure 2. Explanation type code distribution across the three subtasks.

When we considered the explanatory approach of the responses, students shifted from using more everyday explanations towards integrating scientific principles by the revised model. The distribution of Explanation Type for Initial Model is skewed right (see Figure 2), indicating a tendency towards Everyday-type responses. There is a bimodal distribution in the Explanation part of the task, showing high frequencies of Everyday-type and Causal-type responses. This could again be explained by the design of the task as students were asked to explain differences experienced by “home” and “away” players, which might lend itself towards more Causal-type explanations. The distribution in the revised model shows a shift towards more Covering Law-type responses. Overall, this indicates a shift from Everyday-type to more Covering Law- and Causal-type explanations. In Figure 3, we see an illustrative example of a student who begins by drawing upon more everyday language, and by the revised model, has shifted towards including more content knowledge to more fully explain how cellular respiration fuels the football player. Next, we describe how this same example may be interpreted differently using the holistic approach.

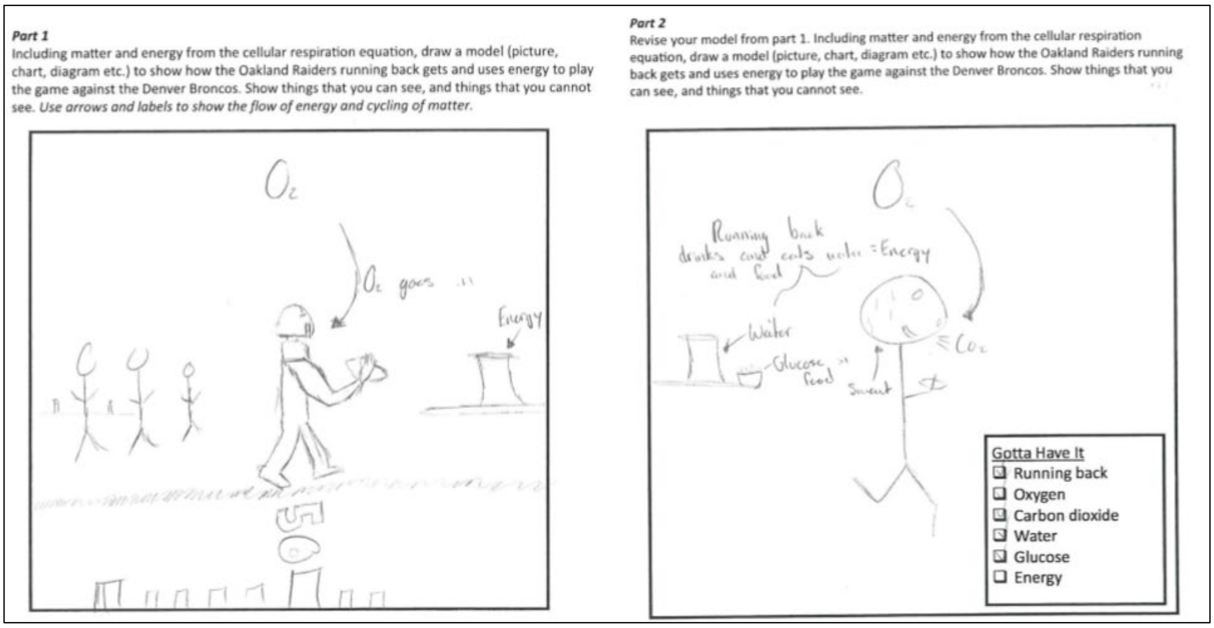

Figure 3. Student work example illustrating shift from initial to revised model.

Holistic approach

To apply the learning progression (LP) code, we looked at all three subtasks holistically and used the context-specific indicators, or “look-fors,” to determine an assigned level. The average learning progression level across all 134 samples of student work was about 1.5 (see Table 3). We can see in Figure 4 that the majority of students were placed at level 1 (n=78), while some students were placed at level 2 (n=41), and a fewer number of students were placed at level 3 (n=15). The high number of students placed at level 1 is not surprising given that this was the first task in the instructional unit. Returning to the student work in Figure 3, this example also highlights the student attending to dissipation of energy through an observable indicator, sweat. Including this element in the model corresponds to a level 3 element on the LP and may otherwise be overlooked by the disaggregated coding scheme.

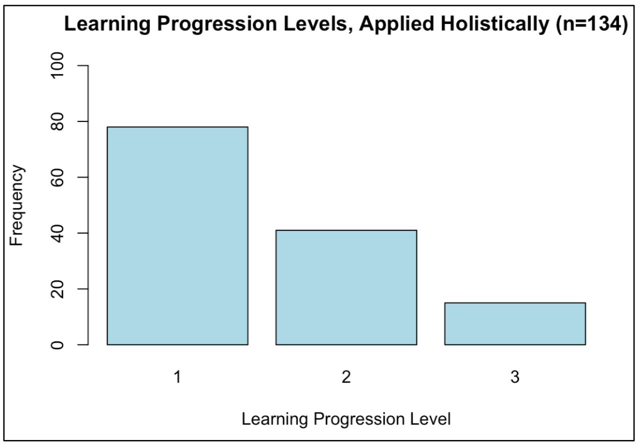

Figure 4. Distribution of holistic approach.

Comparison

When we directly compared each individual student’s disaggregated and holistic score, we found the Pearson correlation coefficient to be 0.78 indicating that the disaggregated and holistic approach are fairly comparable to each other. This indicates that if students are referencing the phenomenon, increasing their DCI understanding, and producing more sophisticated types of explanations, this will likely result in a higher learning progression level. Though, as we can see this relationship illustrated in Figure 5, the variance may be an important consideration for pracitioners. There is more variance with the disaggregated totals and level 1 of the LP, though we see much less variance as we approach level 3. We also see overlap in the disaggregated score between the upper and lower quartiles of adjacent LP levels, so the holistic approach potentially runs the risk of creating distinctions between students whose responses were similar relative to the specified codes. This might indicate a need for a more nuanced approach if analyzing student work falling mostly into level 1. This variance could be explained by students who drew detailed models with multiple elements represented but who may not have been including elements of the LP and might have missed key indicators of energy flow or dissipation, for example. This range may also reflect the difficulty of taking up modeling as a relatively new science practice for teachers and students alike.

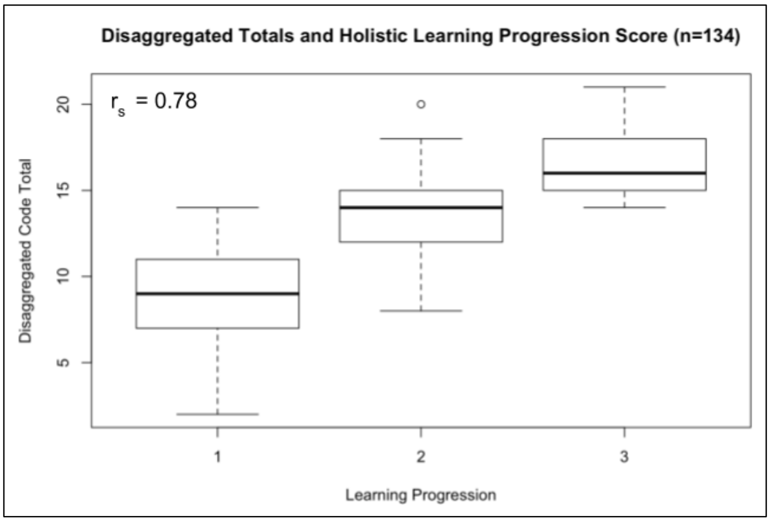

Figure 5. Relationship between disaggregated totals and holistic scores

Overall, our findings suggest that a classroom teacher with upwards of 120 students may find the holistic approach to be the most economical approach to evaluating student work; however, the teacher would want to consider how this approach does not account for changes from the initial to the revised model. Additionally, the holistic approach may be a simpler, mediating artifact for students to reflect on their progress. These results are also consistent with how we might expect the facilitation around a phenomenon to coincide with student gains in modeling energy, where teachers are supporting students in leveraging their everyday understandings towards the goal of modeling energy in the context of cellular respiration.

Discussion

In this paper, we have examined two approaches to scoring multicomponent tasks: a holistic approach, based on an overall appraisal of student engagement in three-dimensional learning, and a disaggregated approach, which provides finer-grained information about student performance. Through our analysis, we found that these two approaches to scoring yielded closely related results; that is, in general, students scoring higher with the holistic approach also had higher overall scores on the disaggregated approach. However, we also found that for students with lower scores in the holistic approach, that were found to be performing at the lowest level of the learning progression, the disaggregated approach revealed more nuances and variations in the nature and quality of their responses. These differences were not as effectively captured when the holistic approach was applied.

These findings have key implications for teacher enactment of three-dimensional formative assessment tasks. Given the complexity of multicomponent tasks and the time-consuming approach of examining individual student responses to different elements of the task, our study suggests that taking a more holistic approach - comparing students' overall responses to a framework that includes disciplinary core ideas, science and engineering practices, and crosscutting concepts together - may be a faster way to determine what students have learned so far, and to identify next instructional steps. However, it also suggests that for students with lower-quality responses, teachers may benefit from spending more time analyzing student responses for additional patterns that could better tailor instruction to meet specific student needs.

At the same time, we note that the benefits of engaging students in complex, multicomponent tasks may far outweigh the challenges of fine-scoring these kinds of tasks. In the context of ongoing efforts to broaden engagement in science learning, particularly for those historically marginalized in classrooms, these kinds of tasks provide important space for students to show what they know and make sense of everyday phenomena. Our disaggregated approach indicated that using these tasks in combination with classroom activities that surfaced and worked with student ideas seemed to support improvement of models and explanations from the first to second part of the task. As such, our analysis indicates that teachers may not even need to closely examine formative assessment tasks such as these, especially since they consume so much time; instead, the teachers may know that the design of the tasks themselves serve a learning function. Future research may more broadly examine this possible finding across a larger range of classrooms and disciplinary contexts.

Which Motivational Factors Predict Pre-Service Teachers' Evidence-Informed Reasoning When Being Confronted With Teaching Problems?

Abstract: Teachers are typically confronted with various classroom-related challenges every day (e.g., students might have difficulties understanding new concepts). However, they rarely reason about such challenges in an evidence-informed manner. Based on the theory of planned behavior, we examined what motivational prerequisites might facilitate pre-service teachers' engagement in evidence-informed reasoning about classroom-related challenges. $N = 157$ pre-service teachers were asked about their motivation to engage in evidence-informed reasoning and analyzed case scenarios of problematic teaching situations in an online learning environment. Structural equation modeling indicated that attainment value, descriptive normative beliefs, and self-efficacy were important prerequisites for the formation of intentions to engage in evidence-informed reasoning and the subjectively perceived behavior in order to solve classroom-related challenges. The findings suggest to help pre-service teachers carefully reflect and discuss what is part of the teacher role and their identification with this role.

Problem statement

Every day, teachers are confronted with various classroom-related challenges (e.g., students might not be motivated to learn, might not understand subject-matter information, etc). In these cases, teachers must decide how to react to these problems. In their decision-making, they are supposed to take scientific theories and evidence into account (e.g., Bauer & Prenzel, 2012). However, teachers rarely use scientific knowledge for teaching-related decisions (Dagenais et al., 2012; Demski, 2018), even though it is believed to improve the quality of their teaching. König et al. (2014) found that having pedagogical knowledge available is associated with the quality of teachers' interpretation of classroom situations. The rare use of scientific knowledge has also been demonstrated for pre-service teachers who are still in teacher training (e.g., Csanadi et al., 2020).

Among the various reasons for the inadequate use of scientific evidence (see below), we suspect motivational aspects to play an important role, especially for pre-service teachers. Thus, the main research question of the present study is: Which motivational characteristics predict pre-service teachers' engagement in evidence-informed reasoning when being confronted with classroom-related challenges?

Barriers to evidence-informed reasoning

When teachers are confronted with classroom-related challenges, scientific evidence, i.e., especially theories from educational and psychological science and corresponding empirical findings, can help to find effective solutions. However, the function of this scientific evidence is not to dictate what a practitioner should do in a specific situation, but to help to prepare for, to justify and to correct educational actions (Neuweg, 2007). Thus, we use the term evidence-informed reasoning for this kind of behavior throughout the rest of this article.

Though considered helpful, empirical evidence shows that teachers rarely apply evidence-informed reasoning when being confronted with classroom-related challenges (e.g., Dagenais et al., 2012; Demski, 2018). The literature offers a variety of reasons: Among them are limited resources (e.g., time constraints, lack of availability of scientific evidence, or lack of external support) or personal factors (e.g., ability deficits in the use of scientific knowledge, or unfavorable attitudes toward scientific theories, see Dagenais et al., 2012). In a comprehensive empirical investigation of reasons for using research-based information in teaching practice, Lysenko et al. (2014) differentiate four factors that predict the use of research-based information by teaching professionals: (a) awareness activities, i.e., being in contact with research and its application potential, (b) organizational factors, i.e., an organizational environment that supports engagement with research-based information by providing resources and structures, (c) opinions about research, i.e., thinking that research is useful and usable, and (d) individual expertise, i.e., individual skills in interpreting and using research-based information. The external factors (a and b) might be particularly relevant for in-service teachers. However, for pre-service teachers, universities should provide extensive awareness for research-based information and organizational structures and resources ideal to engage with research. In contrast, individual factors (c and d) might be relevant already in teacher education. Lysenko et al. (2014) showed that the motivational factor "opinions" (c) predicted the largest amount of variance regarding the use of research-based information. Further, pre-service teachers' abilities (d) are to be built yet and cannot be presupposed. Therefore, within these internal factors, particularly motivational factors might be crucial in understanding why pre-service teachers use scientific evidence to tackle classroom-related challenges or not.

Theory of planned behavior and evidence-informed reasoning

To conceptualize pre-service teachers' motivation to engage in evidence-informed reasoning, we use the theory of planned behavior (Fishbein & Ajzen, 2010) in the present study because the behavior that is to be predicted can be considered planned behavior. Evidence for this comes from a study by König et al. (2014), who investigated teachers' pedagogical analyses of classroom situations presented in video vignettes. They found that the quality of interpretations of these situations is strongly associated with available declarative and explicit pedagogical knowledge. Hence, the authors argued that interpreting classroom situations is a deliberate, effortful process that requires motivation, which should be especially true for beginning teachers. In addition, the theory of planned behavior is well suited to integrate several motivational predictors at the same time, which is necessary to be able to determine the relative importance of each predictor. So far, previous studies only investigated one kind of motivational predictor, or an undifferentiated mixture of several factors, which will be shown in the following.

According to the theory of planned behavior (Fishbein & Ajzen, 2010), a specific behavior is best predicted by the intention to execute this behavior and the perceived behavioral control (see Figure 1). The intention depends on the attitude toward the behavior, the subjective norm regarding the behavior, and the perceived behavioral control. The latter is to be understood as the subjective estimation of the likelihood that one is able to execute the behavior in a given situation. This corresponds to the concept of self-efficacy expectancy (Fishbein & Ajzen, 2010; Bandura, 1997). In the next sections, we will explain these concepts.

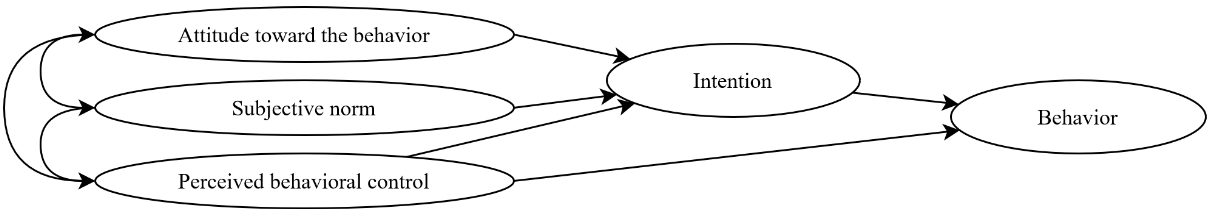

Figure 1. Theory of Planned Behavior (replicated after Fishbein & Ajzen, 2010)

Attitude toward the behavior

Theoretically, the overall attitude toward a behavior consists of various beliefs regarding this behavior, which are salient to the individual in the moment of appraisal. Each belief links the behavior to a specific attribute, e.g., an expected outcome that is a direct consequence of the behavior. Each attribute is of a certain value to the individual, and is realized with a certain likelihood in case the behavior is executed. Thus, the attitude is the sum of all salient beliefs, which in turn represent expectancy*value-interactions of attributes of that behavior.

To conceptualize the global attitude toward a behavior, we use the popular and differentiated distinction by Eccles and Wigfield (2002). The authors distinguish four dimensions of value: utility value, attainment value, intrinsic value, and costs. *Utility value* reflects the perception of the likelihood to which a behavior results in outcomes that lead to consequences positively valued by the individual. *Attainment value* represents how strongly one identifies with the behavior, i.e., perceives the behavior in question as part of one's identity or self. *Intrinsic value* does not describe the value of the consequences of a behavior, but instead the immediate effect of the behavior on oneself while executing it. For example, a behavior might be considered to be interesting or fun. At last, *costs of the behavior*, e.g., time and energy invested, have to be considered as well in order to gather a comprehensive picture of the attitude toward a certain behavior.

In an empirical study, Uhlenbrock (2019) showed that an increase in perceived utility resulted in an increase in several factors regarding the use of evidence-informed reasoning, i.e., strategic knowledge of how to prevent typical errors in evidence-informed reasoning, procedural knowledge of how to identify errors, positive attitudes toward educational science theories, subjective knowledge of educational science theories, and interest in educational science theories. However, the theoretical quality of the written case analysis itself was not influenced by the value manipulations. Kiemer and Kollar (2018) investigated the relation of general attitudes toward research on learning and instruction with actual use of scientific reasoning activities and found a small but significant relation.

Besides these studies, empirical research that investigated pre-service teachers' attitudes toward evidence-informed reasoning is quite scarce. Lysenko et al. (2014) found positive effects on teachers' use of research-based information for several heterogeneous constructs, which mirror the predictors in the theory of planned behavior: The factor "opinions about research" can be considered as an attitude factor because it contains several utility value items (4 out of 7 items). This factor positively and most strongly predicted the use of research-based information. In summary, the literature suggests that attitudes toward evidence-informed reasoning are relevant predictors of the respective intention and behavior.

Subjective norms

As depicted in Figure 1, a second predictor of behavioral intention are subjective norms. In this context, Fishbein and Ajzen (2010) distinguish injunctive and descriptive kinds of subjective norms. *Injunctive norms* reflect what relevant others think what is supposed to be done in a specific situation. *Descriptive norms* represent the perceived actual behavior of relevant others. These two kinds of norms influence behavior of an individual in different ways: While injunctive norms might induce an expectation to receive rewards or punishments when followed or disobeyed, believing that others actually behave in a certain way might offer clues on what is sensible in a specific situation (Fishbein & Ajzen, 2010).

Regarding descriptive normative beliefs, a study of Demski (2018) is informative in the context of evidence-informed reasoning. She asked 1527 teachers and principals with a questionnaire and interviewed 35 of them about reasons for or against the use of knowledge resources based on scientific evidence. The specific use of evidence in order to stimulate new pedagogical behaviors was only reported in schools with the highest average of evidence use in total teaching staff. This effect can be tentatively interpreted as an effect of a school-climate favoring evidence-informed practice: When one's teacher colleagues use evidence in their practice (= descriptive norm), one is more likely to adopt an evidence-informed practice oneself.

Also, in the study of Lysenko et al. (2014), two factors included aspects of subjective norms: In the factor "awareness activities", three out of seven items resembled descriptive normative beliefs (the rest was more about environmental conditions making transfer to practice easier). In "organizational factors", four out of eight items were related to injunctive normative beliefs (the rest was more about opportunities and resources). Both factors were positively associated with the use of research-based information. Thus, overall, the literature suggests both kinds of normative beliefs to be relevant for an engagement in evidence-informed reasoning.

Perceived behavioral control/self-efficacy

The third predictor in Fishbein and Ajzens' (2010) model is *perceived behavioral control*. Though a certain behavior might be attractive (i.e., having a positive attitude toward the behavior) and there might be social pressure to execute this behavior (i.e., strong subjective norms), individuals may still decide not to carry that behavior out. This happens when they believe that their abilities and/or the circumstances prevent successful execution of the behavior in question. Thus, perceived behavioral control is defined as believing that one "is capable of performing a given behavior" (Fishbein & Ajzen, 2010), which is identical to how Bandura (1997) defines the term *self-efficacy* (as long as self-efficacy is understood as a situational, context-specific construct, not a trait). Therefore, we use self-efficacy as the more common term throughout the rest of this article.

The general relevance of teacher self-efficacy for teaching effectiveness is already well established (e.g., Klassen & Tze, 2014). However, a specific investigation of self-efficacy regarding evidence-informed reasoning is scarce. Lawson et al. (2007) investigated self-efficacy and reasoning ability in a sample of non-major biology students, of which a high percentage were pre-service elementary teachers. The self-reported expectancy to perform well in a series of biology tasks they were asked to solve through reasoning was associated with actual reasoning ability measured by a skill test. This finding illustrates that self-efficacy regarding scientific reasoning might be related to actual scientific reasoning. With an operationalization closer to actual teaching practice, Cevik and Andre (2013) had their participants analyze cases including classroom management problems, and decide upon solutions. The quality of decisions was neither associated with self-efficacy ("expectation to do well in this class"), nor with the confidence in the adequacy of their decisions. According to the authors, this might have been due to the general, only domain- but not task-specific nature of self-efficacy measurement. At last, in the study of Lysenko et al. (2014), three out of seven items of the "opinions"-factor focused on expectancy, and the factor "individual expertise" represented abilities and skills necessary to execute evidence-informed reasoning. Taken together, these items could have constituted a self-efficacy factor, whose items are positively related to teachers' use of research-based information.

In conclusion, findings regarding the association between self-efficacy and evidence-informed reasoning about classroom-related problems are mixed: While general reasoning skills seem to be related to self-efficacy (Anderson et al., 1988; Lawson et al., 2007), reasoning in classroom situations seems not (Cevik & Andre, 2013). However, general evidence-informed practice is associated with indicators of self-efficacy (Lysenko et al., 2014). Therefore, we assume that a combination of acting in an evidence-informed way and reasoning about classroom situations is related to self-efficacy if the latter is measured in a context-specific way.

Hypotheses

In summary, a motivational perspective might be a crucial starting point to understand pre-service teachers' engagement in evidence-informed reasoning. Though most of the presented empirical evidence already justifies the expectation that the theory of planned behavior can be used to explain and predict teaching behavior, pre-service teachers' motivation to engage in evidence-informed reasoning has not yet been investigated in a systematic and comprehensive way. Either were the predictors investigated in isolation from each other, or they were grouped into theoretically heterogeneous constructs (Lysenko et al. 2014). Thus, the relative importance of different motivational predictors still needs to be determined. In addition, only a few studies investigated pre-service teachers so far. Thus, our goal was to determine which motivational factors predict pre-service teachers' engagement in evidence-informed reasoning when being confronted with classroom-related challenges.

We establish the following hypotheses:

1. Pre-service teachers' evidence-informed reasoning is predicted by their intention to engage in evidence-informed reasoning and their self-efficacy to perform this behavior.
2. The intention to engage in evidence-informed reasoning depends on various dimensions of (a) attitudes toward evidence-informed reasoning, (b) subjective norms regarding evidence-informed reasoning, and (c) the self-efficacy to perform evidence-informed reasoning.

Method

Sample

Participants were N = 157 pre-service teachers (M_{age} = 22.76, SD = 3.54, 70.1% female) enrolled in two educational psychology classes at two German universities. On average, students were in their fifth semester (M = 4.87, SD = 2.05) without substantial practical experience. Participation in the training elements of the study was a mandatory part of the classes. However, participation in the scientific data collection was voluntary, though no one opted out.

Procedure

This paper reports on data from a larger study that had five measurement points: After a pre-test (t1), in two training sessions (t2 and t3) pre-service teachers received instructional support to enhance their evidence-informed reasoning about the case scenarios. A post-test (t4) and a follow-up (t5) measured the evidence-informed reasoning skills participants acquired over the course of the sessions.

For the present paper, data from t1 (pretest) and t3 (second training session) were used because the following variables were measured at these times only to establish a longitudinal design. The order of assessments was as follows: In t1, after answering demographic items, participants analyzed the first case scenario. After that, they completed a questionnaire directed at measuring the predictor variables of the current study, i.e., attitudes, subjective norms, and self-efficacy regarding the kind of reasoning behavior they just performed. To measure the dependent variables, i.e., intention and subjective behavior, we used data from the second training session to implement a time lag of two weeks. The intentions were measured before the students analyzed the vignettes. The subjective behavior was measured afterwards. To support students in their case analyses in t3, they received evidence texts on CTML, multi-store model of memory, social-cognitive learning, and self-regulated learning, each of about 500-800 words in length, and a couple of reasoning prompts such as "Please explain the problem based on the two evidence texts".

Instruments

Attitudes toward the application of educational science knowledge

Participants indicated on twelve items from 1 (*not at all true*) to 5 (*absolutely true*) how much value they attribute to the structured application of educational science knowledge to teaching problems. The items were adapted from

Stark et al. (2018). All items were phrased using the same sentence starter: "The structured application of educational science knowledge to teaching problems…". Following the model of Eccles and Wigfield (2002), the scale consisted of the facets (three items each) (1) utility value (sample item: "… is useful to learn."), (2) attainment value (sample item "... is personally highly important to learn."), (3) intrinsic value (sample item: "... is very interesting."), and (4) cost (sample item: "... is a waste of time."). A confirmatory factor analysis yielded a good model fit ($X^2(48) = 71.62$, $p = .015$, CFI = .98, TLI = .97, RMSEA = .06, SRMR = .04, all robust estimates) for the theoretical four factor structure, which also was clearly superior to a one-dimensional solution which might have been reasonable regarding the rather high factor covariations. Cronbach's alphas were satisfactory ($\alpha = .78/.82/.85/.84$).

Subjective norms regarding the application of educational science knowledge

On six items (to be answered from 1 = *not at all true* to 5 = *absolutely true*), participants indicated their normative beliefs regarding the structured application of educational science knowledge to teaching problems. The items were specifically developed for this study. The scale consisted of the two facets (1) injunctive and (2) descriptive norms.

Three injunctive normative belief items were phrased using the same sentence starter: "People who have an influence on my later teaching behavior think that I should use educational science knowledge to…" (sample item: "... explain teaching problems."). Three descriptive normative belief items were phrased using the same sentence starter: "I believe that professional teachers use educational science knowledge to…" (sample item: "... explain teaching problems."). A confirmatory factor analysis yielded a very good model fit ($X^2(7) = 9.55$, $p = .215$, CFI = .99, TLI = .99, RMSEA = .06, SRMR = .05, all robust estimates) after inclusion of a residual covariance between the first items of each subscale which is probably due to very similar item phrasing. The two-factor-solution was clearly superior to a one-factor-solution. Cronbach's alphas were good ($\alpha = .88/.86$).

Self-efficacy regarding the application of educational science knowledge

Participants indicated on three items (to be answered from 1 = *not at all true* to 5 = *absolutely true*) their self-efficacy regarding the structured application of educational science knowledge to teaching problems. The items were adapted from the General Self-Efficacy Short-Scale (ASKU; Beierlein et al., 2014). All items were phrased using the same sentence starter: "In the structured application of educational science knowledge to teaching problems,…" (sample item: "... I can rely on my abilities in difficult situations."). Cronbach's alpha was satisfactory ($\alpha = .77$).

Intention to apply educational science knowledge

To measure participants' intention to apply educational science knowledge to teaching problems, we developed five items (to be answered from 1 = *not at all true* to 5 = *absolutely true*) that referred to the dimensions of the problem analysis students were prompted to conduct (e.g., identification of significant instances, explanation of problem). All items were phrased using the same sentence starter: "In the following case analysis, I want to structurally apply educational science knowledge to teaching problems to…" (sample item: "... explain educational problems."). Cronbach's alpha was good ($\alpha = .82$).

Subjective behavior regarding application of educational science knowledge

After the case analysis, participants indicated on five items (to be answered from 1 = *not at all true* to 5 = *absolutely true*) their perceived actual behavior while analyzing the case. The same items as for the measure of intention were used with the sentence starter: "In the previous case analysis, I structurally applied educational science knowledge to teaching problems to…". Cronbach's alpha was good ($\alpha = .84$).

Statistical analyses

To account for sample size restrictions, we used manifest factor scores and applied a stepwise approach to the statistical modeling. First, factor scores were determined by calculating confirmatory measurement models for each predictor group separately and saving the factor scores. In this way, we were able to better represent measurement error compared to an approach using simple means as factor scores. Second, we calculated three separate models predicting intention, i.e., one model with the four facets of attitude as predictors, one with the two kinds of subjective norms, and one with self-efficacy. Third, we entered the significant predictors of each group in the final model (see Figure 2). All CFA and SEM were performed using R [version 4.0.0] with the R-package lavaan [version 0.6-6].

Results

Descriptive results are shown in Table 1. The means of attitude toward the behavior were remarkably high, whereas the other constructs' means were more in the middle of the scale. As expected, correlations within predictor groups were higher than between groups. Intention was associated with almost every predictor except for injunctive norms and self-efficacy. Subjective behavior was significantly associated with every predictor variable except for descriptive norms.

Table 1: Means, standard deviations, and correlations

Variable	*M*	*SD*	1	2	3	4	5	6	7	8
1. Utility Value	4.20	0.59								
2. Attainment Value	4.07	0.63	.76**							
3. Intrinsic Value	3.73	0.74	.64**	.74**						
4. Costs	1.64	0.64	−.58**	−.64**	−.63**					
5. Injunctive Norms	3.95	0.74	.36**	.34**	.27**	−.29**				
6. Descriptive Norms	3.10	0.90	.28**	.25**	.21**	−.22**	.38**			
7. Self-Efficacy	3.62	0.60	.13	.17*	.20*	−.03	.20*	.21**		
8. Intention	4.01	0.50	.36**	.40**	.31**	−.25**	.15	.21**	.14	
9. Subjective Behavior	3.83	0.54	.38**	.37**	.32**	−.18*	.21**	.14	.23**	.50**

Note. $^{*}p < .05$. $^{**}p < .01$.

In the second modeling step, when controlling for covariation with other predictors of the same group, one predictor for each group of predictors was significantly associated with intention. Figure 2 shows the final path model with a reasonably acceptable model fit ($X^2(2) = 5.70$, $p = .058$, CFI = .96, TLI = .79, RMSEA = .11, SRMR = .04). Overall, the associations described by the theory of planned behavior were replicated. Each predictor group contributed to the explanation of intention and subjective behavior: Intention was determined by attainment value and descriptive norms, and subjective behavior was determined by intention and self-efficacy. There was only one exception: Self-efficacy was only directly related to subjective behavior, but not associated with intention.

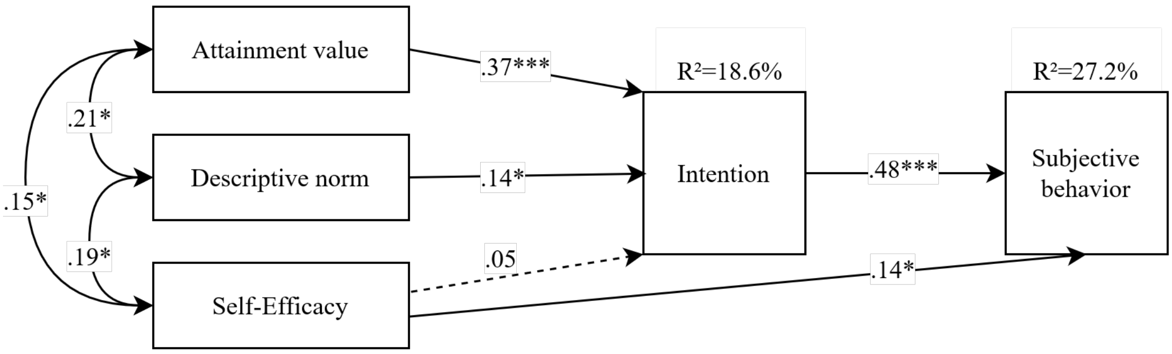

Figure 2. Final Path Model Predicting Structured Application of Educational Science Knowledge to Teaching Problems ($^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$, one-tailed; dotted line indicates non-significant effect with $p = .48$).

Discussion

Our main research question was which motivational factors would predict pre-service teachers' engagement in evidence-informed reasoning when being confronted with classroom problems. In line with the theory of planned behavior (Fishbein & Ajzen, 2010), subjective reasoning behavior was supposed to be predicted by intention to engage in evidence-informed reasoning and self-efficacy (H1). This hypothesis was confirmed by corresponding significant positive regression coefficients. Accordingly, pre-service teachers who intend to engage in evidence-informed reasoning seem to be more likely (to report) to do so when analyzing classroom situations. In addition, the more pre-service teachers feel confident to be able to engage in evidence-informed reasoning in advance, the more they (report to) engage in evidence-informed reasoning afterwards. This association of self-efficacy with subjective reasoning behavior also corresponds to the findings of Lawson et al. (2007) and Lysenko et al. (2014).

Our second hypothesis assumed that intention itself should be predicted by attitudes toward evidence-informed reasoning, subjective norms regarding evidence-informed reasoning, and self-efficacy (H2). This was partly supported in that at least one predictor per group was significantly associated with intention: Among the variables within the construct “attitudes toward the application of educational science knowledge”, attainment value turned out to be a significant predictor. Thus, pre-service teachers seem to form an intention to engage in evidence-informed reasoning especially when they find doing so personally important. Of the two variables measuring subjective norms, only descriptive normative beliefs were significant predictors of intention. This means that pre-service teachers seem to form an intention to engage in evidence-informed reasoning also when they think that (real) teachers typically do so as well. These findings reflect results from other studies that also indicate a positive relation between attitude toward evidence-informed reasoning or, more generally, practice (Uhlenbrock, 2019; Kiemer & Kollar, 2018; Lysenko et al., 2014), and between descriptive norms and evidence-use (Demski, 2018; Lysenko et al, 2014). Yet, the fact that we did not find further significant predictors is opposed to findings indicative of an association of injunctive norms with evidence-use (Lysenko et al., 2014). These findings might be explained by adopting the time perspective of a pre-service teacher: For a person still in teacher training, it might be not so relevant what one can accomplish with evidence-informed reasoning later in their professional life (utility), how much fun it will be to solve a daunting classroom problem with scientific precision (intrinsic), or if it takes a lot of effort or not to engage in evidence-informed reasoning (costs) because all these effects are still far away. In contrast, the reward of feeling like a real teacher might be immediately available just when students behave like they think a real teacher would do. The latter aspect is represented in the descriptive norm, and attainment value represents the intensity of identification with this behavior. Thus, if students think real teachers actually engage in evidence-informed reasoning and at the same time identify with this behavior, then they experience the gratification of living up to their role model as soon as they act in the same manner.

Limitations and conclusions

Of course, our study is not without limitations. Most importantly, since the data is based on self-reports, the association between intention and subjective behavior, especially, might be due to common method bias because of very similar item phrasing, memory effects, and/or social desirability because of the subjective norm to conform with one’s own previous statements. However, we argue that the almost two hours of processing time for the case analyses in between the two measurements should have reduced these effects, because participants should have forgotten what they reported. We are currently coding the participants’ case analyses, so objectively measured behavioral data will be available to corroborate our findings in the future. In general, the effects we found in this study can be considered as rather stable since there was an interval of two weeks between measurement of the predictors and intention. However, the very same interval might also be the reason why there was no effect of self-efficacy on intention: In the meantime, participants’ engagement in another training session might have changed their initially perceived level of competence, thus possibly affecting the intention to engage in evidence-informed reasoning during the next session which was measured in the present study. Finally, we did not specify the kind of teaching problem or the theoretical background useful to analyze it before we assessed pre-service teachers’ motivational predictors to engage in evidence-informed reasoning. Consequently, our measurement might not have been sensitive to moderating effects of the kind of problem or theoretical topic.

As an implication for future research, the relatively superior importance of attainment value in contrast to utility value sheds new light on the findings of Uhlenbrock (2019), who manipulated utility value to increase engagement in evidence-informed reasoning, but who did not find corresponding effects for all representations of evidence-informed reasoning: Maybe, an induction of attainment value instead of utility value might have resulted in more pronounced effects.

The present findings may also inspire the design of teacher education curricula. When aiming at motivating future teachers to make evidence-informed decisions, we empirically derived indicators where to start best. Uhlenbrock (2019) increased the utility perception of educational science theories with a value-inducing intervention. However, our results point to a different approach: As attainment value seems to be the better predictor of the intention to use and the subjective use of educational knowledge when analyzing teaching problems, and as descriptive normative beliefs also play an important role in that context, we assume that involving professional teachers in motivating pre-service teachers might be most promising: If actual teachers model evidence-informed reasoning in authentic situations, pre-service teachers should be more motivated to reason in an evidence-informed way themselves than if university instructors focus on utility or on expectations of what teachers should do that are formulated by the government or research (Bauer & Prenzel, 2012). Thus, teacher training curricula should not prescribe an engagement in evidence-informed reasoning, but should show real teachers in action as role models that are applying evidence-informed reasoning when confronted with classroom-related problems.

Growing Mindsets: Debugging by Design to Promote Students' Growth Mindset Practices in Computer Science Class

Luis Morales-Navarro, University of Pennsylvania, luismn@upenn.edu
Deborah A. Fields, Utah State University, deborah.fields@usu.edu
Yasmin B. Kafai, University of Pennsylvania, kafai@upenn.edu

Abstract: Mindsets play an important role in persevering in computer science: while some learners perceive bugs as opportunities for learning, others become frustrated with failure and see it as a challenge to their abilities. Yet few studies and interventions take into account the motivational and emotional aspects of debugging and how learning environments can actively promote growth mindsets. In this paper, we discuss growth mindset practices that students exhibited in "Debugging by Design," an intervention created to empower students in debugging—by designing e-textiles projects with bugs for their peers to solve. Drawing on observations of four student groups in a high school classroom over a period of eight hours, we examine the practices students exhibited that demonstrate the development of growth mindset, and the contexts where these practices emerged. We discuss how our design-focused, practice-first approach may be particularly well suited for promoting growth mindset in domains such as computer science.

Keywords: debugging, motivation, growth mindset, computer science, e-textiles

Introduction

Debugging—the process of identifying and fixing problems and errors that prevent a program from working as expected—is an inevitable and intrinsic part of learning computer programming. Furthermore, it is an essential computational thinking practice (e.g., Brennan & Resnick, 2012) that is often overlooked in K-12 classrooms (McCauley et al., 2008). As Papert (1980) remarked, "errors benefit us because they lead us to study what happened, to understand what went wrong, and, through understanding, to fix it" (p. 114). However, for some students, encountering bugs can generate emotional responses such as fear and anxiety that lead to disengagement and the avoidance of computer programming (Scott & Ghinea, 2013). Prior studies provide ample evidence of how mindsets play an important role within computer science (Burnette et al., 2020, Nolan & Bergin, 2016), as students with growth mindsets perceive bugs as opportunities for learning, and those with fixed mindsets become frustrated with failure and see it as a challenge to their intelligence. Thus, in computer science (CS), promoting growth mindset in the classroom is important since debugging is such an essential practice, and persevering through debugging is critical to students' learning.

Debugging is an area that is particularly difficult for students to learn and challenging for teachers to teach (McCauley et al., 2008). Yet, few studies provide a holistic approach to debugging that takes into account the "inextricable relationship between thinking and emotion" in learning how to persevere and handle failure (DeLiema et al., 2020, p. 210). Traditional pedagogical approaches to debugging tend to involve, highly limited, linear strategies to finding bugs in code (e.g., Silva, 2011) in constrained programming contexts that provide well-timed feedback (e.g., Luxton-Reilly et al., 2018). These approaches usually include only bugs designed by instructors, limiting students' agency over bugs. Further, they only attend to isolated, cognitive aspects of debugging in limited scenarios. In contrast, positioning learners as designers of bugs for their peers could give them greater power over bugs and allow them to be creators and not just solvers. We propose that having students design buggy (rather than functional) computational artifacts for their peers to solve may help promote students' growth mindsets in practice.

In this paper, we examine the growth mindset practices that students exhibited when creating buggy electronic textiles (hereafter e-textiles) projects for their peers to solve and, subsequently, fixing each other's projects. We report on four cases of student groups engaging in our implementation of "Debugging by Design" (DbD), an open-ended design learning activity, in a high school CS classroom over a period of eight hours (Fields & Kafai, 2020). In DbD students work with e-textiles—which involves creating wearables using programmable microcontrollers, sensors and actuators that can be sewn into fabrics (Buechley et al., 2013). Making an e-textiles project not only includes designing functional circuits but also writing code that controls interactions—thus, providing multiple opportunities for bugs in crafting physical artifacts, designing circuits and programming (Searle et al., 2018). Early evidence suggested that when students consciously created bugs, they improved their abilities to detect and fix bugs, collaboratively solved problems, and increased their confidence in debugging

(Fields et al., in press). As such, we observed students to see if and when they demonstrated growth mindset practices. Drawing on the analysis of student team interactions in designing bugs for others; we address the following research questions: (1) What practices do students exhibit that demonstrate the development of growth mindset? (2) When do growth mindset practices emerge during the DbD unit?

Background

Our work builds on longstanding motivational research on the impact of student self-beliefs in learning. Dweck (2006) organized opposing self-beliefs on the capability to develop competencies and qualities in what she calls growth and fixed mindsets. Learners with a growth mindset, those who believe their competencies and capacity can change and be developed over time, have higher resilience in challenging environments than those with fixed mindsets (Yeager & Dweck, 2012). In CS education, growth mindset has gained relevance as learning to code is challenging and encountering bugs is inevitable. For instance, Murphy and Thomas (2008) argue that in computing, while students with a growth mindset perceive bugs as opportunities for learning, those with fixed mindsets become frustrated with failure and see it as a challenge to their intelligence. This resonates with early debugging research which identified that while some learners see bugs as inherent and exciting challenges of learning to code, others become frustrated, perceiving bugs as negative reflections of their performance (Perkins et al., 1986). Indeed, among novice learners, encountering bugs and trying to fix them can generate feelings of helplessness, frustration and anxiety, and promote a fixed mindset (Scott & Ghinea, 2014; Nolan & Bergin, 2016). Furthermore, these feelings and self-beliefs can lead to disengagement, attrition, and the avoidance of computer programming (Scott & Ghinea, 2013; Margolis et al., 2017).

The existing, but limited, research on growth mindset interventions in CS education has yielded promising results that suggest that interventions seem to increase interest, particularly among novices (Burnette et al., 2019). Most of these interventions happen within learning environments, in which teachers delivered information about growth mindset research through videos, lectures, and readings followed by reflective writing and “saying is believing” exercises (Simon et al., 2008; Cutts et al., 2010; Rangel et al., 2020). Other interventions also included testimonials of professional role models that talked about growth mindset and offered tips for success (Burnette et al., 2019; Quille & Bergin, 2020). However, all of these approaches prioritize telling students about growth mindset rather than facilitating student experiences that support its development in practice. Only one intervention proposed the use of a problem-solving checklist for students to track their progress as they programmed projects (Loksa et al., 2016).

Noticeably absent from current research are interventions that actively promote and examine growth mindsets in action. Some attention has been given to how to integrate mindset research in the classroom. For instance, Campbell and colleagues (2020) identified practices, which they call behaviors, that characterize growth mindset in learning activities and situate them within larger learning theories and Haimovitz and Dweck (2017) examined how adult and socialization practices can foster growth and fixed mindsets in children. Building on these works, we investigate growth mindset in action by analyzing how students practice it while engaging in an intervention that centers around debugging. In DbD, we promote growth mindset by putting learners, rather than teachers or researchers, in charge of creating intentional problems and turning bugs into a feature of the learning product rather than a stumbling block. Our research of DbD in this paper focuses on the growth mindset practices that students exhibited when designing bugs for others and solving bugs, as well as the situations where these practices emerged.

Methods

Context and participants

We situated our DbD activities within the e-textiles unit of Exploring Computer Science (ECS), an inquiry-based CS curriculum that is committed to broadening participation in computing through a building talent approach that addresses the structural inequities and beliefs systems that limit participation from historically marginalized groups (Margolis et al., 2017). Within ECS, the promotion of a growth mindset among teachers and students plays an important role, as it puts equity first by considering that all students with access to quality education can grow in engagement and capacity (Margolis et al., 2017). During the e-textiles unit, students work on four open-ended, interest-driven physical computing projects; a paper card with circuits, a bracelet with parallel circuits, a collaborative class mural that has light patterns controlled with switches and finally a hand-crafted sensor to control light effects (see Fields & Kafai, 2020). In these open-ended physical computing activities—that integrate coding, building circuits, and crafting—facing failure and unanticipated challenges is expected and inherent in the learning process (Searle et al., 2018). Students have to think through the distributed nature of physical computing, where problems are spread across different modalities, and must iteratively identify bugs, generate solutions, and run tests (Searle et al., 2018).

DbD was intentionally situated between the third and fourth projects in the E-Textiles unit, after the collaborative class mural described above. This allowed students to bring their experiences with bugs from earlier projects to their DbD designs, and to apply any knowledge gained from DbD to their final project. The activity was designed to take place during eight 50 minutes class sessions over a period of two weeks. At the beginning of the activity students discussed with their partners and the whole class different errors and problems they encountered when working on e-textiles projects. Then, student groups came up with a list of bugs they wanted to include in their designs. After receiving approval from their teacher, students began working on their buggy designs, or DebugIts. Once they finished the buggy projects, they exchanged them with their peers and spent one class period debugging their peers' projects before presenting their solutions to the class.

In Spring 2019, Ben, a teacher with three years of experience in e-textiles that helped co-develop the curriculum, implemented DbD with his students at a high school located in a metropolitan school district in the West Coast of the United States. The class included 11 girls and 14 boys between 14 and 18 years old. Of these students, 72% spoke a language other than English at home, 80% had no previous CS experience, and 80% had family members with at least some college education. The class was ethnically and racially diverse, with 48% of students identifying as Latinx, 36% as Asian American/Pacific Islanders, 8% White, 4% other, and 4% not reporting their race/ethnicity. From the class, four collaborative groups were selected by the teacher for further study in order to represent a range of student interaction and performance including two groups of two students (Evelyn and Nicolás, and Liam and Sophia) and two groups with three students (Lucas, Emma and Lily, and Georgia, Gabriel and Camila) (all participant names in the paper are pseudonyms).

Data collection and analysis

To investigate the growth mindset practices that students exhibited and the situations, challenges or contexts where these practices seemed to emerge; data for analysis was drawn from in-class videologs and observations (recorded in daily field notes) of participants working on their projects as well as interviews (n=10 students). This multiple-source approach provides a fuller picture of what happened in the classroom and the growth mindset practices that students exhibited. Data sources were sorted by date, student group of interest and type.

Data was analyzed in two steps. First, a chronological reading of sources from two student groups focused on inductive descriptive coding (Saldaña, 2013), through which a coding scheme for moments of interest where students exhibited growth mindset practices was developed. These descriptive codes were then clustered into similar categories to detect patterns and interrelationships. This process of clustering was informed by prior theories and previous research on mindset practices and behaviors (Campbell et al., 2020; Dweck, 2006; Dweck, 2000). Following, a coding scheme was developed and discussed with two researchers familiar with the data. After receiving feedback, the coding scheme was revised. In the second round of analysis the coding scheme was applied across all groups through a deductive reading.

Findings

Our analysis in this paper focuses on the growth mindset practices that students engaged in while planning, designing, and solving their DebugIts. This allowed us to see intersections between the cognitive challenges in designing code, circuit and crafting bugs and the motivational and emotional challenges often associated with growth and fixed mindset. We identified five emergent growth mindset practices or behaviors. These practices include: 1) choosing challenges that lead to more learning, 2) persisting after setbacks, 3) giving and valuing praise for effort, 4) approaching learning as constant improvement, 5) developing comfort with failure. While the first four practices coincide with the practices proposed by Campbell and colleagues (2020), the last practice emerged inductively from videolog coding. In the following sections we introduce these five practices, providing examples for each, followed by a case study of how they emerged in the context of one team, and then conclude with an overview of how these practices were distributed across four teams of students.

Growth mindset practices

Choosing challenges that lead to more learning

Throughout DbD, students purposefully chose challenges that led them to learn new things, "throwing themselves wholeheartedly into difficult tasks—and sticking with them" (Dweck, 2000, p. 3). As an example, when making a DebugIt, Emma, a student with very little sewing experience sewing, decided to take on the challenge of sewing a complicated project that required creating one circuit across two different heart-shaped pieces of felt, with lights on one sheet and most of the sewn circuitry on the other sheet. As she struggled sewing the microcontroller on one sheet of felt and connecting it to the LED lights on the other sheet, Emma reflected, “probably I should do more craft,” a recognition of her need for more expertise in sewing (Lesson 3, Video). Yet even knowing she had little experience in this area, Emma was the one that proposed arranging the electronic components in this spatially complex way and, mischievously, to embed a short circuit between the two layers of felt. This is just one of many examples of ways that students consciously chose challenges that led them to deeper learning.

Persisting after setbacks

Setbacks are a normal part of debugging that can cause frustration and at the same time provide opportunities for students to persist. For this practice we identified two subcategories: preceding frustration and persistence. Frustration as part of the learning process is meaningful because it creates opportunities for students to persist and, as Dweck (2006) writes, “to turn an important setback into an important win” (p. 93). We observed how frustration sometimes precedes persistence and other times co-occurs in instances of persistence. As an example of frustration preceding persistence, when fixing a circuitry bug in her sewing, Evelyn exclaimed: “This is too much… I don’t know what’s wrong with it.” She was upset and frustrated. Her partner, Nicolás, encouraged her, but she insisted she didn’t know how to fix it. Nicolás offered to help, “déjame [let me] look at it” (Lesson 7, Video). Twenty minutes later, and after working on other aspects of the project, Evelyn persisted and continued folding and bending the artifact to get it to work until the lights turned on. During this process, Evelyn discovered that the problem was in loose connections of the conductive thread. “I could have fixed it a long time ago, if I knew the connections were all loose” she reflected (Lesson 7, Video). On a different instance, Evelyn seemed upset dealing with a bug and Nicolás encouraged her: “You can fix it! Fix it!” (Lesson 7, Video). In this instance, frustration and persistence co-occurred. Despite her frustration, Evelyn kept sewing and managed to get the lights to turn on. Thus, with encouragement from her partner, as Evelyn persisted, she evaluated and analyzed the problems, looking for alternative ways to solve them. These two examples illustrate the occurrence and the co-occurrence of frustration and persistence; and how setbacks, although frustrating, became opportunities for learning in the process of creating and solving bugs.

Giving and valuing praise for effort

While working on their DebugIts, students praised each other’s efforts, strategies and process. This kind of praise fosters mastery-oriented responses when facing difficult problems (Dweck, 2000). In one instance, after finding several unintentional problems in her circuit Emma reflected and suggested a possible solution: “I always forget to tie the knots, it’s so annoying, I better tie them as I go along.” Lucas praised her proposed strategy and the process of getting to it by saying, “Smart thinking!” (Lesson 3, Video). In a different instance, in Emma’s group, praising and encouraging effort demonstrated what Love (2019) calls cultural legacy, that is the traditions and customs of culture, in self-beliefs. Emma had to add a short circuit bug in which two threads intersected. Her teammates, Lucas and Lily, were worried they would finish on time. “What time is it? Do you think I’ll finish?,” Emma asked. In response, Lily and Lucas started chanting Dolores Huerta’s “¡Sí se puede!” (Yes we can) to encourage and praise Emma’s effort (Lesson 4, Video). The “¡Sí se puede!” chant, which emerged in the 1970s during the civil rights movement for farm and immigrant worker rights in the Southwestern United States, is an expression for encouraging effort and persistence with great cultural and historical significance in Latinx communities. This praise and encouragement from peers for effort promotes growth mindset by framing setbacks and challenges as inherent aspects of learning that can be overcome with persistence.

Approaching learning as constant improvement

Student teams also embraced learning as constant improvement and looked for ways to improve their projects and their competence. As Dweck (2000) argues, this reflects a desire to learn, get smarter, and acquire new skills. We see this when, after Lucas finished writing the code and reported that he had made all the suggested changes, Emma responded by saying, “let me see what other things we can do” and proposed several ways they could improve the project (Lesson 3, Video). In a complementary episode later, after Emma tested whether the stitches and knots were strong enough by turning the project upside down, Lucas suggested they checked the wires to make sure they were not touching, taking on the role of looking for opportunities for improvement (Lesson 3, Video). In these two examples we can see how students supported each other in seeking opportunities to improve their performance and saw the goal of learning as constant improvement and not just showcasing or achieving a certain level of performance.

Developing comfort with failure

Developing comfort with failure generates opportunities for learners to embrace and overcome mistakes with proper motivation and guidance (Dweck, 2000). When learners are worried about failure they are more likely to develop a fixed mindset and question their ability while learners with a growth mindset “see their own failures as problems to be solved, and they see other people's failings that way as well" (Dweck, 2000, p. 88). In DbD, we identified that students were comfortable with failure particularly by not being afraid of being wrong when: 1) asking questions and requesting feedback, 2) sharing failure with their peers, and 3) embracing failure and imperfection as part of the process. Sophia, for example, not afraid of being wrong when sewing a circuit, asked Liam "Can positive and positive cross each other?" (Lesson 1, Video). This is one of many instances in which students constantly requested feedback from peers without any fear of being wrong. Further, when learners encountered failure while working on their projects, it was not uncommon for them to openly share failure with their peers. As an example, Lucas shared his coding mistakes saying "Oh! I messed up! Wrong in the coding!" (Lesson 3, Video), while Evelyn shared "Oh my god! I was going to keep going without sewing up the light!" when she noticed a gap in sewing and laughed at her own mistake (Lesson 4, Video). These are instances of seeing failure as something worth sharing. Furthermore, students embraced imperfection and failure as a feature of their projects—separate from the intentionally designed bugs. For instance, when Emma noted that the two heart-shaped pieces of felt of the group's project were not perfectly aligned she described them as "a little bit off, but it's okay". She also went on to offer a simple, imperfect solution, saying "we'll just cut it off, it doesn't have to be perfect" (Lesson 4, Video). These are some examples of how students were not afraid of being wrong, "messing up," making mistakes and or having imperfect projects. Developing comfort with failure helped students reframe failure as a setback they could overcome and as opportunity for learning.

A case study of growing mindsets

One case study group—Georgia, Gabriel and Camila—illustrates how the five growth mindset practices described above came up in the context of the DbD unit. Growth mindset practices appeared from the very beginning of the group's work. As the group brainstormed what they wanted to make for their DebugIt and the bugs they wanted to include (see Figure 1), Camila suggested an area that went beyond the group's current expertise: making a piano and coding music. Gabriel hesitated to agree, "we've never used music before and we have two days" (Lesson 2, Video): they had not learned about coding music previously in the class and did not have much time to figure it out by themselves, but they did have access to a supplementary instructional guide on music with e-textiles. Ben, their teacher, who had overheard the conversation about coding music, encouraged the team to do it and even to create a bug related to music. They decided to play Twinkle, Twinkle, Little Star and to have Gabriel code it. This required understanding how to code notes by defining pitch and duration in numerical values with new commands in Arduino. Although Gabriel shared with his peers that he had "no clue how to code music," he took charge of this new challenge and learned about frequencies and tempo with an instructional guide. Of note, Gabriel's choosing to take on this new challenge happened in the context of both peer and teacher support.

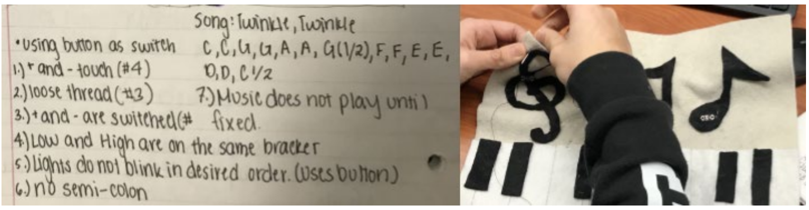

Figure 1. Georgia, Gabriel and Camila's DebugIt: (1) Left: list of bugs included in their project plus order of tones; (2) Right: Georgia sewing musical notes above the keyboard.

As Camila and Georgia worked on crafting the keyboard, Georgia became frustrated when gluing the musical notes: "I can't do this, I physically can't do this" (Lesson 3, Video). It was hard for her to calculate how much glue to apply on the felt. "I don't like glue, now it's a mess," she complained, having poured glue all over the project. Georgia's frustration created an opportunity for her to persist and overcome this setback, which she did with the support of her peers. Camila provided just-in-time praise for effort to motivate her friend to keep going: "you're almost there Georgia, that looks very good" (Video Lesson 3). Georgia persisted and tried different strategies: first using a piece of felt to apply it and then using the tip of the bottle to spread it. The latter strategy worked, and satisfied, she praised her own work "this [keyboard] looks so good!" (See Figure 1). We can see here how two mindset practices worked together: frustration generated opportunities for persistence, and just-in-time praise for effort helped reframe setbacks as inherent aspects of learning that can be overcome with persistence.

As work on the project continued, Georgia shared her mistakes when she took on a challenge that led to more learning. Georgia, who had little experience sewing and crafting, told her peers "I'm just warning you I'm not the best at sewing" as she started sewing the circuit. Not afraid of failure, Georgia shared her problems with Camila who helped her tie knots and make her connections tight. They shared their failures with each other and laughed together about the unintentional mistakes they made. Camila, for example, shared that she sewed an LED to the wrong pin of the microcontroller and Georgia shared that she sewed an LED backwards. Comfortable with failure, when students chose challenges that led to more learning, they embraced mistakes and overcame them.

When coding *Twinkle, Twinkle, Little Star*, Gabriel persisted after encountering many setbacks and frustration. He did not know how to trigger the song to play, but after fixing many unintentional bugs in his code and asking the teacher many questions he managed to make the microcontroller play music. When it worked, with frustration, he said "I have no clue why it sounds so hideous, this is devilish trap music" (Video Lesson 4). His peers agreed and did not like the sound. Yet, he persisted and continued working on improving the song and on the last day of designing he was able to play it to the teacher and his peers. The music became an Easter egg in the project: they used the light sensor on the microcontroller to trigger the song. Gabriel explained: "if you take the flash on your phone and put it on your CP [microcontroller] it'll make sounds happen." This is an example of how when students chose challenges that led to more learning, their frustration became an opportunity to overcome setbacks, persist when things do not go as expected, and approach learning as constant improvement. The team embraced learning as constant improvement in other instances as well, when they looked for ways to improve their project and their performance. When Gabriel was done with the code he insisted they had to test it to see if it worked as expected and if not to fix it. They tested several times, and every time they came up with new ideas of how to improve the project.

Growing mindsets across groups

This case illustrates how students engaged with growth mindset practices in the context of DbD. We identified 75 instances in which Georgia, Gabriel and Camila engaged with these practices. They were not the exception. The four groups we analyzed engaged in all identified growth mindset practices in 230 instances. Figure 2 shows the frequency of instances of each practice by group of interest as well as information about the context of each instance, when they occurred (e.g., when planning the project), and who was involved (e.g., teacher and learner). As we saw in our case study, students engaged with growth mindset practices through peer-to-peer and learner-teacher interactions when planning their projects (e.g., making a circuit diagram), making buggy projects, and debugging their peers' projects. Most of the instances of growth mindset practices identified (56%) occurred when learners made buggy projects for their peers to solve. Most of the instances coded (78%) occurred when peers interacted with each other, although we also identified growth mindset practices when students worked alone or in learner-teacher interactions.

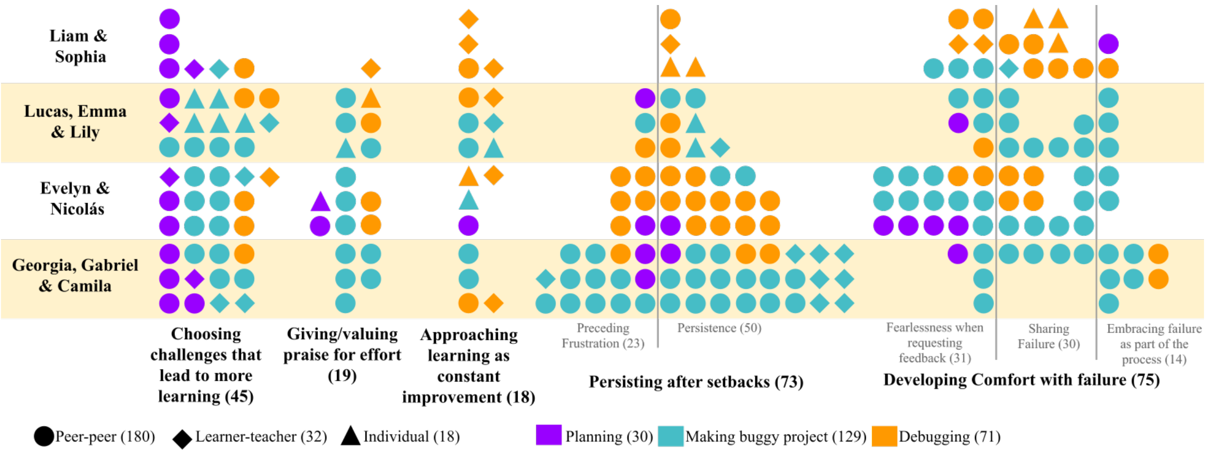

Figure 2. Visualization of instances of growth mindset practices by student group; color indicates when the instance occurred, and shape indicates who was involved.

Discussion

We analyzed the growth mindset practices that students exhibited in DbD, an intervention designed to empower learners in becoming more familiar, comfortable and capable with debugging. In the following sections, we discuss our instructional design rationale, what we learned about developing students' growth mindset practices, and directions for further research.

In designing DbD, we built on a longstanding tradition of constructionist activities that put learners in control of their own learning by designing applications for others (Harel & Papert, 1990, Kafai, 1995) and extended this concept by shifting the focus from designing functional artifacts to designing non-functional, or buggy, projects. By making learners designers rather than finders of bugs, we created an environment in which students were in control of naming and creating mistakes. DbD provides a compelling example of what Dweck and Yeager (2019) called for, “an examination of the mindsets conveyed by or embodied in the environments that students (or adults) are in” (p. 490). This proactive design approach contrasts with previous growth mindset interventions where teachers explicitly instructed students on growth mindset theory or practices (e.g., Simon et al., 2008). While explicit instruction and reflection on growth mindset can certainly help students, we suggest that our design-focused, practice-first approach may be particularly well suited to domains like CS that involve iterating, testing, and debugging. Putting students in charge of designing mistakes for their peers to solve could be applied to other areas of CS education as well other disciplines.

Furthermore, our analysis of four groups of students provided insights into how learners develop their growth mindsets and become more comfortable with debugging. Students engaged in practices such as choosing challenges that led to more learning, praising effort, approaching learning as constant improvement, persisting after setbacks, and developing comfort with failure. This last practice complements those practices mentioned in Campbell and colleagues’ (2020) framework of practices for growth mindset learning activities, acknowledging mistakes and failures as “an intrinsic part of the learning process” (Papert, 1980, p. 153). Combined, these practices promote debugging as a holistic process that involves thinking and emotion (DeLiema et al., 2020), rather than a basic skill for identifying isolated problems. Of further note are the critical roles that peer collaborations and teacher support played in the DbD unit. The development of the observed growth mindset practices mainly occurred through interactions with peers, while they made buggy projects together. But these peer-supported practices did not happen accidentally, our implementation of DbD was conducted by a highly experienced teacher that promoted a classroom culture that encouraged student collaborations, legitimized student expertise, and modeled comfort with failure (Fields et al., in press).

We reported on the first classroom-based implementation of DbD. Further studies should examine how other teachers can foster growth mindset practices when applying the unit in their classrooms. In addition, we must examine the impact of DbD on students’ continued programming efforts and compare it to students who did not engage with the unit. Furthermore, we need to examine how growth mindset practices exhibited in the classroom relate to the perceived growth mindset of students and teachers as measured in self-reported instruments. Lastly, the idea of making students designers of bugs, or mistakes, is not limited to CS education and could also be applied to other STEM contexts in which students design artifacts. Students can benefit not only from designing applications but also from designing mistakes—both are and should be an intractable part of any learning production.

Abstract: We designed and examined a knowledge-building environment in which representations of a learning analytics tool called Idea-Friend Maps (IFM) and opportunistic collaboration were used to scaffold progressive knowledge building in authentic scientific practices. Fifty-two Grade-Five students in a large class in China participated and worked on *Human Input and Output*, mediated by the online platform Knowledge Forum. Student groups were provided with analytics information generated from Knowledge Forum discourse as IFM to support cross-group fertilization and progressive knowledge building. Quantitative results using social network analysis of word networks show collective knowledge advancement and changing trajectories over time. Qualitative analysis using a framework demonstrates how students pursued related ideas from other research groups, identified the current state and future direction of community knowledge, and created new knowledge by crossing boundaries with IFM and opportunistic collaboration. This study sheds light on the role of learning analytics and opportunistic groups to scaffold young children to engage in authentic scientific practices like scientists.

Introduction

How to equip learners with capacities for knowledge creation and innovation has become a great challenge facing education (OECD, 2019). *Knowledge Building* is a major model in this field, which aims to facilitate the transformation of education by introducing the concept of knowledge-creating communities (Scardamalia & Bereiter, 2014). In such a creative community, the teacher plays a facilitator's role, while the students' collective epistemic agency is stimulated to advance collective knowledge. Therefore, an online platform Knowledge Forum® was developed to allow students to post problems, co-construct explanations, and conduct sustained inquiries for collective knowledge advancement. Notably, knowledge building is premised on the notion of scientific communities (Bereiter et al., 1997). Engaging students in the kind of knowledge building just like scientists who progressively extend existing knowledge rather than seeking a static source of "truth" (Bereiter et al., 1997) is of much importance, as highlighted by recent reforms in science education (NGSS Lead States, 2013). Though this approach has attracted great interest, progressive knowledge building in scientific practice is often limited in pre-designed activities and tasks (Chinn & Malhotra, 2002).

Concerning scientific practice, Nielsen (2013) points out the role of science as a form of communicative action (scientific communication) in promoting progressive knowledge building. He further classified lab (group) communication and peer review as essential elements of scientific communication. However, how different scientist groups engage in cross-group scientific communication for progressive knowledge building in authentic scientific practices is worth further inquiry. Moreover, while flexible engagement and emergent inquiries in knowledge building are encouraged, students may feel it challenging to understand the changing status and the cutting edge of collective knowledge, similar to scientists' need to identify promising research directions. These issues bring out the questions of how to identify the promising and emergent ideas in the socio-cognitive knowledge-building environment for collective knowledge advancement. Thus, two design considerations were inspired: (1) how to design social configurations to help students engage in scientific communication like researchers; (2) how to visualize changing ideas by learning analytics so that students could identify and pursue collective ideas like researchers.

Zhang et al. (2009) examined various social configurations, including fixed groups (students working in fixed groups), interactive groups (working in fixed groups and also carrying out cross-group activities), and opportunistic groups (working temporarily in groups formulated by interests). Results indicate that opportunistic groups yielded the most creative learning outcomes. Thus, opportunistic collaboration formulated through establishing and disbanding new groups based on emergent goals is considered a promising solution to scientific communication and collective knowledge advancement.

Knowledge Building Discourse Explorer (KBDeX) (Oshima et al., 2012), a learning analytics tool, was adapted in this study, drawing upon the research on agency-driven and choice-based learning analytics in knowledge building (Zhang & Chen, 2016). It has been used in extensive research to visualize the process of knowledge-creating discourse. Specifically, this tool can visualize the changing social networks of *students*, *words*, and *discourse*, as well as their centrality metrics. To visualize the similarities and differences in ideas between students, Ma et al. (2017) adopted the betweenness centrality of the student network, coupled with the existence and mechanism regarding the connection of different ideas by rotating leaders (students with high values of betweenness centrality). To visualize collective ideas, Teo et al. (2018) used KBDeX to help teachers understand students' collective discourse and reflect on how to further the cutting edge of collective knowledge. To visualize idea boundaries, Yuan et al. (2019) used the betweenness centrality of word network to identify the new ideas developed through crossing community boundaries. Most of the current knowledge-building studies focus on the use of KBDeX by researchers, with increasing attention paid to that by students (Wise, 2020).

Accordingly, a knowledge-building environment was created using the representations of KBDeX called Idea-Friend Maps (IFM) and opportunistic collaboration to support progressive knowledge building. This paper focuses on examining a three-pronged knowledge-building framework for scientific practice, which includes: (1) how students work like researchers to pursue different but related ideas, (2) how students identify the current state and future direction of the community, and (3) how students create new knowledge by crossing knowledge boundaries. Specifically, the role of IFM and opportunistic collaboration in fostering progressive knowledge building when students were working on Knowledge Forum was examined. The research questions are: (1) Did student groups advance collective knowledge over time, and what were the different trajectories among groups? (2) What were the key areas of collective inquiry, and how did the class community make collective knowledge advancement? (3) In what ways did students engage in progressive knowledge building, supported by IFM and opportunistic collaboration?

Methods

Participants

Fifty-two Grade-Five students from a primary school in Nanjing, Mainland China, participated in the research project and worked in 12 groups, each with 4-5 students; they had previous experience working on Knowledge Forum from Grade Four. The first author served as their science teacher throughout the study period.

Design of knowledge building and the Idea-Friend Maps environment

The 12 groups of students worked on Knowledge Forum (KF) for 9 weeks, exploring *Human Input and Output* and conducting different experiments as what scientists do in their research process. They were enriched with KF activities such as posting questions, generating theories, co-constructing explanations, revising theories, and collaborating with other groups. We designed the *Idea-Friend Maps* tool to provide students with analytics information from KF discourse. KBDeX is a social network analysis tool from which the word networks were extracted and provided as diagrams for students. The circles are all the keywords in KF writings: the red and yellow circles denote keywords having or having not been discussed. Students were also provided with prompt sheets with scaffolds (e.g., What are your group's idea friends? What topics do they come from? What questions you want to research now?) to support cross-group fertilization.

We designed three levels of IFM (i.e., the group, community, and knowledge building) and combined them with different social configurations in three phases (Figure 1). IFM diagrams (KBDeX word network of their KF writings) were provided to help students work on (a) problems across groups (group), (b) problems for the class (community), and (c) a rise-above *Progressive Knowledge Building* view on emerging new problems in different phases. Initially, they worked as interactive groups to explore different but related ideas, and then as opportunistic groups to conceptualize the current state and future direction of community knowledge, as well as to identify new gaps by crossing boundaries. Table 1 depicts the three-levels of IFM, including challenges, types, key features, as well as examples of how to use them.

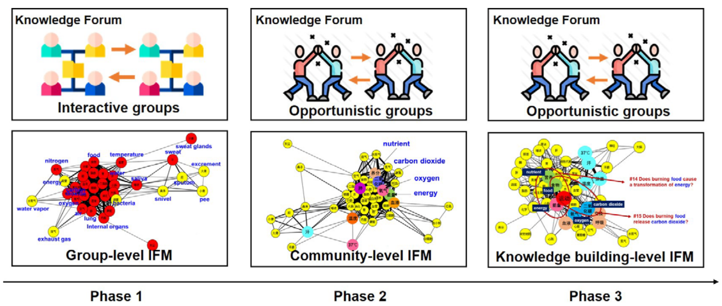

Figure 1. The combination of IFM and social configuration design

Table 1. The framework of the three-level Idea-Friend Maps

Challenge	Type	Key feature	Example
How to work like researchers as a community to pursue different but related ideas?	Group-level	Distinguishing ideas from other groups	Students work in *interactive groups* to identify group problems first and then bring new concepts and promising ideas from related groups.
How to identify the current state and future direction of community knowledge?	Community-level	Highlighting key problems in the community knowledge	Students work in *opportunistic groups* to conduct meta-discourse to criticize and synthesize different theories, identify connections between problems, and create new promising ideas.
How to sustain progressive knowledge building by crossing knowledge boundaries?	Knowledge building-level	Highlighting key problems in each research area to clarify knowledge boundaries	Students work in *opportunistic groups* to identify new gaps and propose higher-level ideas by crossing knowledge boundaries.

In Phase 1, using the group-level IFM, students conducted cross-group interactions to explore 8 research fields (views), including *Food Input*, *Excreta Output*, *Gas Input*, *Gas Output, Digestive System*, *Respiratory System*, *Cardiovascular System* and *Others* (Figure 2(a)). In Phase 2, they used the community-level IFM to research the community's key problems and worked in opportunistic groups on the *Community Building* view (Figure 2(b)). In the last phase, using the knowledge building-level IFM, they conducted sustained inquiries on the *Progressive Knowledge Building* view (Figure 2(c)). After identifying new gaps, putting forward theories, and finding evidence, they researched conclusions and pointed out future directions.

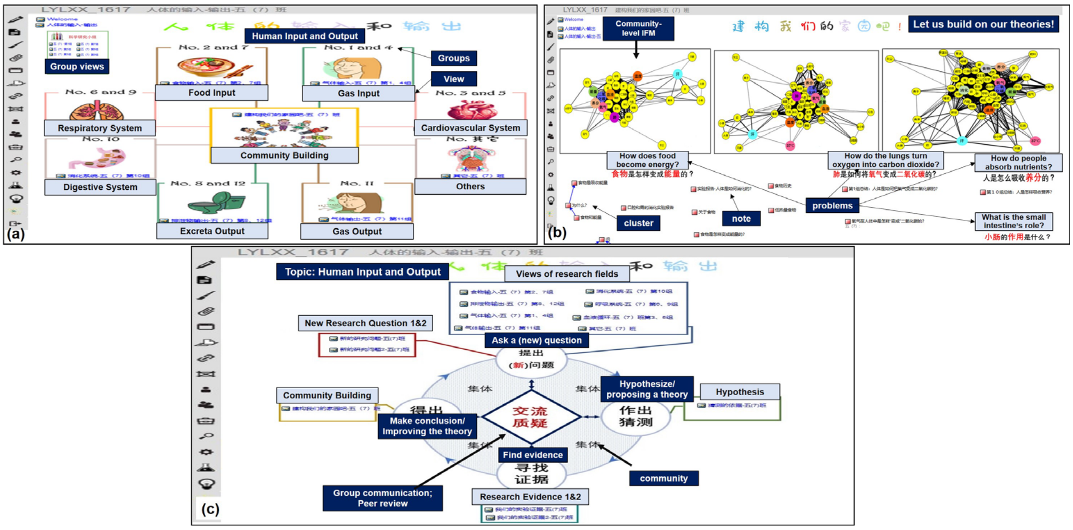

Figure 2. Research field views (a); *Community Building* view (b); *Progressive Knowledge Building* view (c)

Data sources and analyses

Data sources include KF writings, videos of classroom discourse, and knowledge artifacts. Pre- and post-tests of scientific understanding changes and the role of IFM have been reported previously (Feng et al., 2020). This paper focuses on knowledge-building dynamics supported by IFM and assesses collective knowledge advancement using Total Degree Centrality (TDC). Based on knowledge-building research on KBDeX (Oshima et al., 2012), a higher TDC means a denser social network of domain keywords and discourse, denoting more collective knowledge advancement (Oshima et al., 2017). Using the KBDeX networks, we can track how different groups evolved in their collective KF work across phases and studies. Additionally, qualitative analyses were conducted to investigate the key areas of collective inquiry, the developmental trajectory of collective inquiry and collective knowledge advancement, and in what ways students worked like scientists to engage in progressive knowledge building.

Results

RQ1: Did student groups advance collective knowledge over time, and what were the different trajectories among groups?

The changing word networks of different contributing groups exported from KBDeX are depicted in Figure 3, where red and yellow circles represent the keywords having or having not been discussed. Overall, there is an upward trend in TDC and network density across 3 phases (42.76 in Phase 1, 61.84 in Phase 2, and 67.81 in Phase 3). As a higher TDC score means more collective knowledge advancement (Oshima et al., 2017), this finding suggests group advancements in the collective knowledge of *Human Input and Output* over time.

We also identified three contributing groups (i.e., high, medium, and low) and tracked their trajectories in relation to different levels of IFM and social configurations. High/medium/low contribution group refers to the extent to which their KF notes added value to the TDC of the whole class. With the intervention of the *group-level IFM* and *interactive groups* in Phase 1, the high-contribution group presented a centralized network of red circles, demonstrating the ability to connect different subtopics. In contrast, the medium and low-contribution groups showed different locations of red circles, indicating the ability to conduct interactive activities to explore ideas from different subtopics but with limited connections of those subtopics. Moreover, the high-contribution group's contribution to collective knowledge advancement was two times more than that of the medium and low-contribution ones. In Phase 2, with the intervention of the *community-level IFM* and *opportunistic groups*, both medium and low-contribution groups doubled their contribution to collective knowledge advancement compared with Phase 1. Furthermore, the medium-contribution group showed a much more centralized network of red circles, comparable to that of the high-contribution group. In Phase 3, with the intervention of the *knowledge building-level IFM* and *opportunistic groups*, both the medium and low-contribution groups showed comparable group contribution and centralization of red circles to the high-contribution group. These results suggest the role of different levels of IFM and social configurations in scaffolding different contributing groups for collective knowledge advancement.

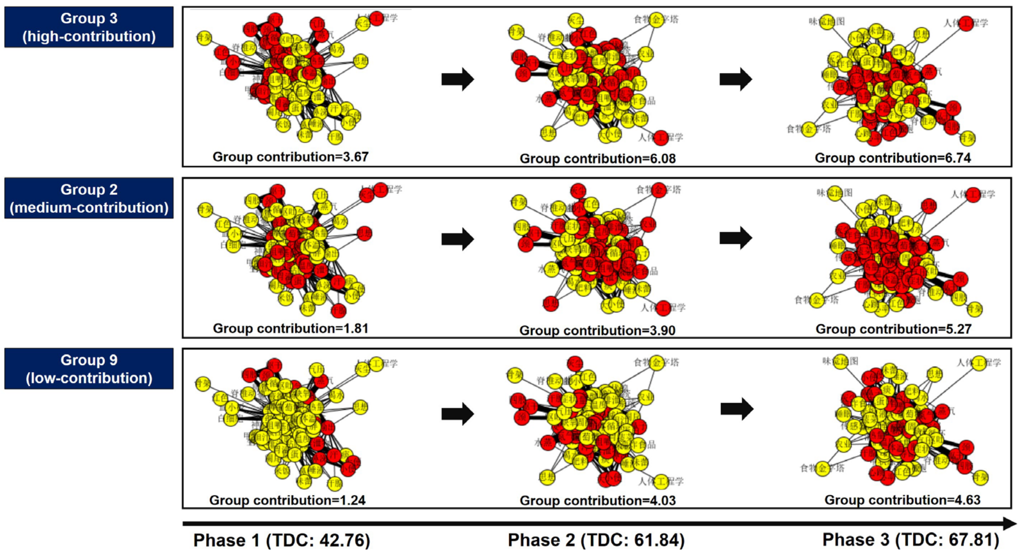

Figure 3. Changing networks and group contributions to collective knowledge advancement over phases

RQ2. What were the key areas of collective inquiry, and how did the class community make collective knowledge advancement?

Key areas of collective inquiry of class community

Figure 4 shows the socio-cognitive community dynamics of how student groups engaged in progressive knowledge building towards collective knowledge advancement under three levels of IFM and social configurations, akin to how scientist groups work, focusing on different topics but also culminating in different foci. Overall, the *Human Input and Output* developed from 8 fields in Phase 1, including *Food Input*, *Excreta Output*, *Gas Input, Gas Output*, *Digestive System*, *Respiratory System*, *Cardiovascular System*, and *Others*. Later, these fields were synthesized into 4 in Phase 2, including *Food Input and Digestive System*, *Gas Input/ Output and Respiratory System*, *Cardiovascular System*, and *Excreta Output*. Each covered several problems. For instance, in the research field of *Food Input and Digestive System,* problems of "What is the small intestine's role (Problem #1)?" "How do people absorb nutrients (Problem #2)?" and "How does food become energy (Problem #3)?" were targeted. In Phase 3, all the research fields rose above to one primary research field of *Food/Gas*

Input/Output: Reactants and Products of Digestion. Finally, this problem moved forward to the future direction of *Metabolism*, to explore problems such as "Where does the food turn into energy (Problem #19)?"

Developmental trajectory of collective inquiry and collective knowledge advancement

In Phase 1, students conducted interactive collaboration with other groups. For example, Group 2 took the research field *Food Input* and interactively explored other fields. In Phase 2, students first identified seven key problems of the four research fields from IFM diagrams and posted those problems on KF. For instance, "How do the lung turn oxygen into carbon dioxide (Problem #4)?" was identified in the *Food/Gas Input/Output* field. After tackling those community problems, they proposed new problems. Afterward, students worked in opportunistic groups joining different members to solve those key problems and propose new questions. In Phase 3, working in opportunistic groups, members from Group 2 first came to *Food Input and Digestive System* to explore the problems of "How do people absorb nutrients (Problem #2)?" "How do people feel food (Problem #8)?" and "What changes in body temperature after eating food (Problem #9)?" Later, they worked at the cutting edge and crossed boundaries of food and gas fields, solving Problems #14 to #16, such as "Does burning food cause a transformation of energy?" Finally, they proposed rising-above problems of *Human Input and Output*, pointing to the future direction of *Metabolism.* With the use of different levels of IFM and scaffolds (e.g., where would you move next?), students were able to have cross-group fertilization and synthesis for collective knowledge advancement.

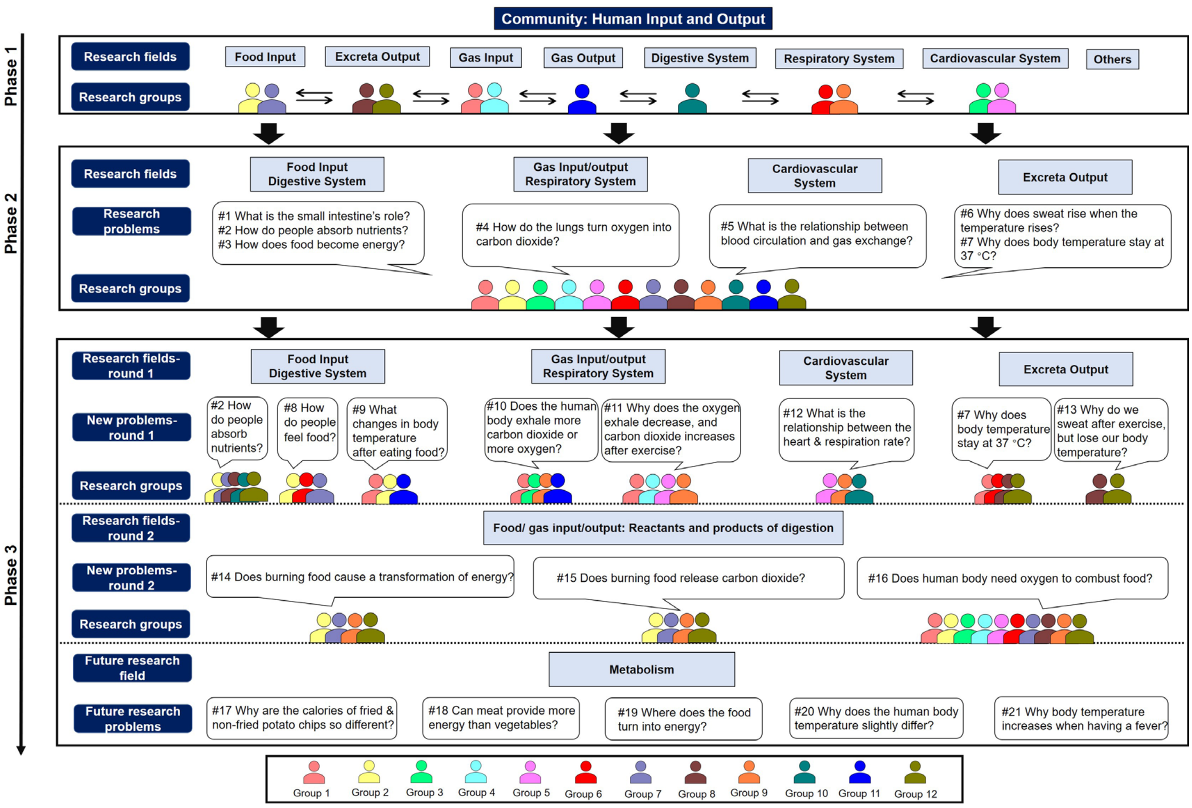

Figure 4. Socio-cognitive community dynamics for progressive knowledge building

RQ3. In what ways did students engage in progressive knowledge building supported by IFM and opportunistic collaboration?

Using the framework (Table 1), we explored in what ways students worked like scientists, including pursuing different but related ideas, identifying the current state and future direction of community knowledge, and creating new knowledge by crossing boundaries supported by IFM and opportunistic collaboration.

How to work like scientists as a community to pursue different but related ideas?

A group-level IFM of Group 2 (generated from KBDeX) is depicted in Figure 5(a), where the red and yellow circles denote those keywords on KF used and not used by Group 2, respectively.

Among the circles, yellow circles near the red ones represent "idea friends." The "friendship" among ideas is analogous to the proximity of scientific ideas in research. As described in Figure 5(a), students in Group

2, who were responsible for *Food Input*, first identified “bacteria,” “energy,” and “excrement” as idea friends, and then moved to *Excreta Output* for relevant information on KF. Furthermore, they also proposed new connections under the group-level IFM. For instance, after identifying “bacteria” as an idea friend and proposing a new keyword of “Escherichia coli,” they made a focus and constructed connections among other idea friends. Notably, after comparing and combining what they identified from IFM with their knowledge, they drew a flow map (Figure 5(b)) to visualize their theory of “How bacteria help digestion in intestines, release energy, as well as absorb nutrients and release useless materials.” These results suggest that students with the support of the group-level IFM could identify important gaps to pursue different but related ideas.

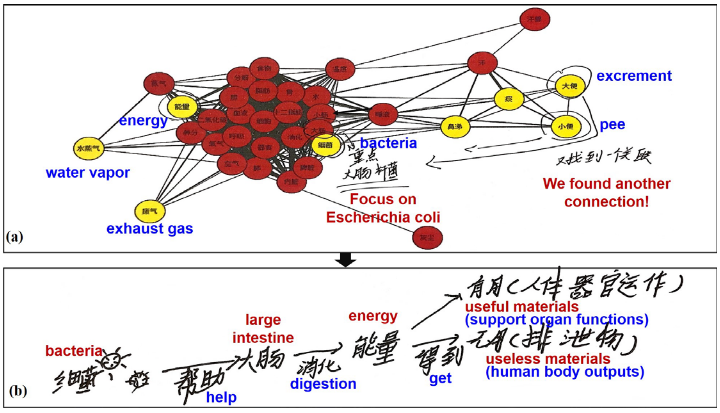

Figure 5. Examples of writings and drawings from Group 2 on the prompt sheet of the group-level IFM

How to identify the current state and future direction of community knowledge?

A *community-level IFM* is presented in Figure 6(a), in which the key problems were identified by the community and marked by *colored* circles (except yellow ones that represent potential explanations of the key problems). For instance, the pink circle “oxygen” presents the key problem “How do the lungs turn oxygen into carbon dioxide (Problem #4 in Figure 4)?” It can be synthesized by students in opportunistic groups with the surrounding yellow circles.

Supported by the community-level IFM that shows different problems and gaps, students started exploring the class community’s key problems. Then, they worked in opportunistic groups to reframe the collective ideas and propose new questions on the KF. For instance, from the perspective of the transformation of food/gas inputs to outputs by human organs, an opportunistic group synthesized the questions “How do people absorb nutrients?” and “How do the lungs turn oxygen into carbon dioxide?” They selected and referenced some related KF notes from the whole community, proposing a new theory of “Oxygen supports breathing, food provides energy, and water maintains human health,” and then completing a new KF synthesis note, as shown in Figure 6(b). These results indicate the process of students identifying the current state and future directions with the support of the community-level IFM.

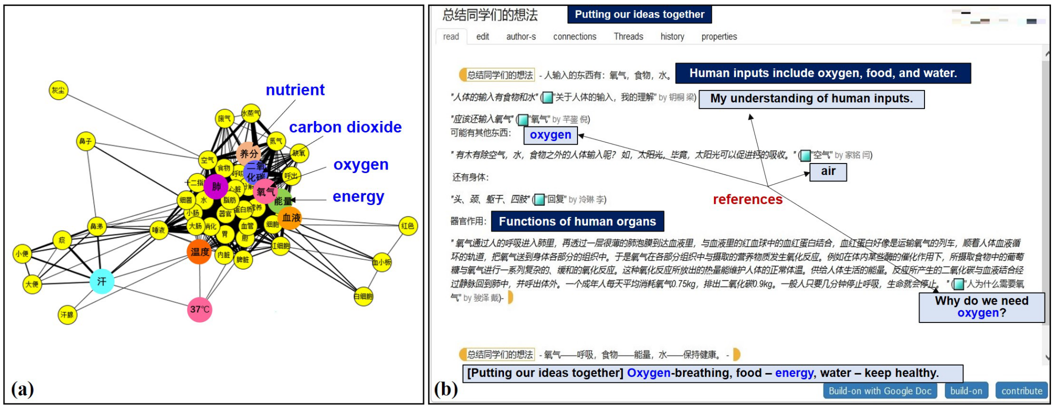

Figure 6. Example of an opportunistic group’s conceptualization of the community state

How to create new knowledge by crossing knowledge boundaries?

Figure 7 displays a *knowledge building-level IFM*, where circles with the same color (except some yellow ones as they might be bridging ideas for different research fields) refer to the key ideas identified from the same research field. For instance, the new problem “Does burning food cause a transformation of energy (Problem #14 in Figure 4)?" is incurred by the connection of the green circle "food" and the pink circle "energy." The new problem, "Does burning food release carbon dioxide (Problem #15 in Figure 4)?" comes from the connection of the green circle "food" and the dark-blue circle "carbon dioxide."

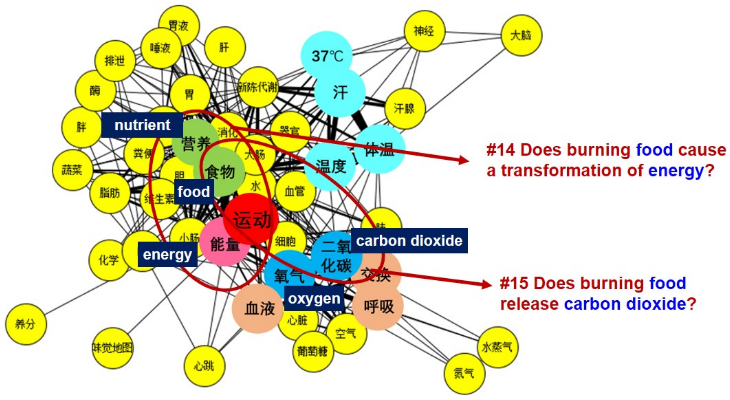

Figure 7. The knowledge building-level IFM used to visualize idea boundaries

After identifying and exploring the current community's key problems on *Human Input and Output*, students worked in much more in-depth opportunistic groups to conduct sustained inquiries of new research problems. Here, students c736, c742, and students from other groups as a new opportunistic group are taken as an example. With the knowledge building-level IFM, this opportunistic group observed the close distance between "food" and "energy" and then proposed the new problem of "Does burning food cause a transformation of energy?" They measured the water temperature with a temperature sensor before and after heated by the burning potato chips (Figure 8(a)). They found that even 0.3 g fried potato chips could boil 5 ml of water, indicating the release of energy from food burning. Later, they found the close distance from the blue circle "carbon dioxide" in the research field of *Gas Output* to the green cycle of "food" in *Food Input*. Then they proposed a new problem by crossing the two research fields: "Does burning food release carbon dioxide?" Using the carbon dioxide sensor, they found that potato chips consume oxygen while releasing carbon dioxide and energy during burning process (Figure 8(b)). Knowledge building is progressively deepened as problems solved and new ones emerged - students rose above to the higher research field of reactants and digestion products, eventually proposing the concept of metabolism and identifying new problems for future direction. Surprisingly, students c736 and c742 came from Group 9, which was a low-contribution group identified in RQ1. However, results from RQ1 also show their improved group contribution over time and comparable contribution to the high-contribution group in the final phase. These findings suggest that with the support of the knowledge building-level IFM and opportunistic collaboration, young children can engage in progressive knowledge building through crossing boundaries.

Conclusion and discussion

This study contributes to the literature of scientific practice and knowledge building - by investigating how young children were supported by the innovative design of learning analytics representations (IFM) and opportunistic collaboration to work as a community just like scientists. Results show how elementary-school children engaged in progressive knowledge building, specifically pursued different but related ideas, identified the current state and future direction of community knowledge, and created new knowledge by crossing boundaries with the support of IFM and opportunistic collaboration. This study suggests engaging students in deep social-community interaction such as authentic scientific practices, just like researchers involved in intentional scientific communication. The analogy to scientists' working practices presented in the framework of IFM (Table 1) will help educators scale such social configurations for innovative knowledge building. Theoretically, the framework can be examined for the socio-community dynamics of knowledge emergence. Additionally, it can also guide students to engage in fixed groups, interactive groups, and opportunistic groups for deepening inquiry into specific topics gradually. Their knowledge-building process can be sustained through collective inquiry, just like how researchers work on innovative projects.

Abstract: This paper examines how teacher guided play can support inquiry while learning science. Guided play has been positioned as a balanced approach to supporting learning in ways that value the curious, playful, and child-directed characteristics of play. We present interaction analysis of two cases of teacher guided play, where we examine how teachers guide students in ways that not only lead to instructional goals but support the playful exploration that is important in students' learning experiences. Findings in this paper reveal how guided play changes participation and discourse practices as teachers incorporate these open forms of learning into classroom spaces.

Introduction

In recent years, there has been a growing interest in the importance and potential of young students learning through play (Hirsh-Pasek, et al., 2009; Papademetri & Louca, 2020; Youngquist & Pataray-Ching, 2004). This work has provided evidence that play can support the development of young learners' creativity, engagement, socio-emotional competence, and cognitive development (Ashiabi, 2007; Nicolopoulou, Barbosa de Sá, Ilgaz, & Brockmeyer, 2009; Pyle, DeLuca, & Danniels, 2017; Saracho, 2012). Within learning contexts, particularly in schools and classroom settings, there has been a focus on *guided play*, where teachers and educators can engage in play to guide young students in learning. Our study blends adult guidance, the investigation of complex scientific phenomena, and opportunities for young students to playfully explore these science concepts.

While recent literature on guided play shows how it can scaffold and lead to learning (Fisher et al., 2011), we further unpack how play—specifically how *paidia play* can be guided in ways to support students in investigating conceptual ideas. We do this by examining how guided play transforms what participation and discourse can look like as students engage in more playful and spontaneous forms of learning and sensemaking. This paper will examine how guided play can function as an agentic space where students have access and opportunities to participate, explore, and learn science in different ways. We ask: *How does guided play support students' participation and discourse while learning science?*

Theoretical framework

Play

Although there is little consensus on how to define play, one broad distinction relevant to our analysis is Caillois' (1961) concept of paidia play. Paidia play is characterized by its spontaneity, with any rules for the play arising from within the play activity itself. Examples include playing in a jungle gym, rolling down a hill, or wrestling with a friend. Unlike games (often called *ludus* play) there are no pre-established winners or losers, nor any one right way to play. One way to think about paidia play is as an orientation towards one's activity, rather than any defining characteristic of the activity itself. As Bateson (1955, pp. 41) put it, play is a "meta-communicative stance" towards one's own activity where the meaning of actions is flexible and negotiable. For example, in a play fight, a punch is meant to stand in for a real punch, but it does not mean the same thing as it would in a real conflict. Colloquially, we might say that paidia is a term that emphasizes the 'playfulness' dimension of play. For our analysis, we examine interactions where students are taking a playful, paidia stance towards their science inquiry, and how teachers guide students within this playful frame to support learning.

Socio-dramatic play

While some contend that socio-dramatic play and paidia play are synonymous (Frasca, 2003), it is important for our analysis to distinguish how socio-dramatic play is often structured and governed by implicit socio-cultural rules. For example, children who play house might take on the role of "parents" by pretending to drive to the store, hold a baby, or make dinner. We think of socio-dramatic play as a subset of paidia play in the sense that it can also unfold spontaneously in playful ways, but the addition of explicit socio-cultural roles and rules shifts how it influences and organizes children's activities and learning.

For young children, play serves as one of many cultural tools that provides access to participation in cultural practices mediated by social norms, rules, and histories. During socio-dramatic play, a young child can negotiate the cultural rules and roles that may not be accessible to them in their everyday lives. For example, Vygotsky (1980) described two sisters who play "sisters" together. Typically, being sisters is in the background of their every experience—rarely do they make visible the meaning of their relationship. However, playing "sisters" foregrounds the rules of sisterhood (e.g., dressing and talking alike or sharing parents). Thus, playing as "sisters" transforms sisterhood from an implicit relationship to an explicit social role with corresponding rules and norms. These rules that ground sisterhood provide these young children with an opportunity to socialize in culturally relevant ways. That is, making the rules explicit in play reflects how they perceive sisters should behave in the real world. The importance of socio-dramatic play is therefore not only for fun and whimsy, but the opportunity to reflect, re-enact, and explore experiences rich with shared sociocultural rules, roles, and norms.

Socio-dramatic play also gives children the opportunity to explore imaginary situations that are not a part of their everyday lives. In order to help them gain access to an imaginary situation that they otherwise would not be able to explore, children use familiar objects and ideas in new ways. For example, in socio-dramatic play a signifier (e.g., a stick) can be used to represent the meaning of the signified (e.g., a horse) (Vygotsky, 1967). Vygotsky described this process as a pivot, where children could attach abstract meaning to known objects in order to satisfy the imaginary situation in play. Thus, when a child plays "horsie," they can imagine and use the stick to represent the horse. This expands the possibilities of their immediate environment and provides opportunities to use everyday experiences to help investigate the rules of a situation that they are not yet able to fully understand. In this way, play acts as a leading activity of childhood, driving the development of new and more complex cognitive processes in young children as they enact playful versions of situations that are just beyond their reach (Duncan & Tarulli, 2003).

Teacher guided play

Guided play differs in that the goals of the play activity include adult-driven learning goals. It "melds exploration and child autonomy with the best elements of teacher-guided instruction" (Weisberg et al., 2016, pp. 1). Research on guided play activities have shown to be effective and promising for education, including positive learning outcomes in literacy, math, and science learning (Bellin & Singer, 2006; Enyedy, et al., 2017; Sarama & Clements, 2002). When learning through guided play, students can gain agency, control, and choice in their learning experiences (Jensen, Pyle, Alaca, & Fesseha, 2019; McInnes, Howard, Crowley, & Miles, 2013). This is what makes guided play a powerful learning and sensemaking experience that connects with students' lived experiences and provides them with opportunities where we can playfully challenge and build on their ideas and thinking.

During guided play, the role of the teachers and how teachers provide guidance can differ and vary based on classroom and student needs. For example, a common method of guiding play is when teachers provide materials and set up the classroom environment for children to play in (Neuman & Roskos, 1992). Relevant to our analysis, teachers can also provide guidance by participating *with* students in the play activity; "teachers enhance children's exploration and learning by commenting on children's discoveries; by co-playing along with the children; through asking open-ended questions about what children are finding; or exploring the materials in ways that children might not have thought to do" (Fisher, et al., 2011, pp. 343). This version of guided play, where teachers actively co-participate alongside students in the activity, is an untraditional way of participating in classroom discourse and disciplinary work.

In this paper, we question how participation and discourse in inquiry learning can shift and transform as a result of both teachers and students co-participating in a playful learning environment. Our paper presents analysis of two cases of paidia play, where teachers guided learning within these playful environments in different ways. In the first case, we present an example of paidia play where the teacher suggests an emergent and playful goal that fluidly becomes part of inquiry. In the second case, we present an example of socio-dramatic play, a version of paidia play where students spontaneously organize their actions according to the implicit socio-cultural rules of a role. In both cases, we analyze how teachers balanced students' agency while working towards broader curriculum goals and examine how guided play shifts disciplinary discourse, participation, and learning.

Science through technology enhanced play

To set up the classroom environment in ways that promote playful activity within scientific inquiry, we leverage technology developed for the Science through Technology Enhanced Play project (Danish, et al., 2015; 2020). The project is a mixed reality learning environment that uses motion tracking cameras (labeled K1, K2, & K3 in Figure 1) to allow students to playfully embody and explore science concepts. For this study, students engaged in guided play as water particles. The environment tracks and transforms students' movements into a digital simulation of water particles moving on a screen (Figure 1). We first fostered playfulness by asking our students to imagine themselves shrinking down to the size of microscopic water particles. Guided by their classroom teacher, students took on these microscopic roles to discover the rules that governed changes in states of matter as they moved in coordination with their peers. The mixed reality technology also guided students' play by providing real time feedback to students about how their different movements can create and change the states of matter represented on the shared screen.

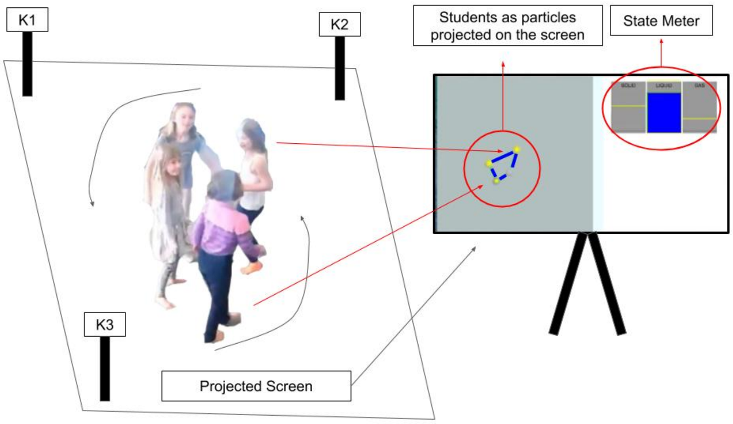

Figure 1. Students in the mixed reality environment

The facilitators used the mixed reality environment and playful prompting (e.g., having students crawl through a hula hoop dubbed the "Particle Shrink o Rator") to set up an imaginary situation in which students can investigate the rules of particle behavior, such as how speed, distance, and energy impact the way that matter changes into different states. Across the unit, students explored both macroscopic (e.g., observable properties such as solids keep their shape) and microscopic features of states of matter (e.g., particles in a gas move quickly). Students spent the majority of the unit exploring how water particles change at the microscopic level and describing the rules for each state in terms of the speed and the distance between particles. Students were given agency to explore the simulation and notice different aspects of state change as they interacted in fairly freeform ways. As the unit progressed, the teachers added increasing amounts of structure to students' play in order to move them towards more formal modeling practices.

In both their play and modeling, students were encouraged to move in ways that reflected how water particles behave in solid, liquid, and gaseous states. Through their explorations, they uncovered the underlying rules that created each state of matter in the simulation by using the visualizations of the technology, namely the color of the bond or a state meter. To create a solid, students moved slowly (often vibrating in place) while spreading out to have some distance in between peers. This created white colored particles on the screen. To create a liquid, students slowly weaved around the play space while keeping a closer distance to create blue particles (see Figure 1). Finally, to create a gaseous state of matter, students ran around the play space at a fast speed with plenty of distance between peers to create red particles in the simulation.

Methods

Students in this study were from five mixed-aged classrooms of 1st and 2nd graders (ages 6-8) from two different sites in the United States. Three of the classrooms were from a large city on the west coast (site 1), while two classrooms were from a smaller midwestern city (site 2). The focus of our analysis was how teacher guided play provided students with new and unique opportunities to participate in science learning.

Using interaction analysis (Jordan & Henderson, 1995), we analyze and present the data in detail to explore the mechanisms through which teachers noticed and supported playful interactions to guide students towards scientific inquiry. We first reviewed and content logged the larger video data corpus across all five classrooms, which consisted of 24 classroom videos of approximately 45-60 minutes in length. Based on our initial video viewing, two classrooms were selected for more detailed analysis, one from Site 1 and one from Site 2, because the teachers in these classrooms engaged in the most amount of paidia play. We then marked moments in these classrooms to create a collection of teacher-guided paidia play— including both spontaneous playful moments (e.g., moving like a caterpillar) as well as more structured versions of paidia play (socio-dramatic play). Within these moments, we focused on episodes where teachers guided and used these playful moments to build towards scientific learning goals. These episodes were transcribed using the Jeffersonian transcription system (Jefferson, 2004) and analyzed through multiple rounds of video viewing with the research teams at both sites to examine the ways in which the different teachers guided students' play. We present our analysis to illustrate the potential of guided play that we found to be reflective of the larger corpus of data. Each case examines ideas that were proposed during paidia play that resulted in teachers guiding students towards greater understanding of the scientific phenomena.

Findings

Case 1.

In our first case we present analysis of discourse from an example of teacher guided paidia play at site 1, where the teacher (Ms. Jones) guides her students in inquiry by spontaneously pitching a playful idea to encourage her students to explore science concepts. The analysis details how students used the colors that were represented in the visualization (Figure 1) to make observations, conjectures, and conclusions on how speed and distance between particles result in each state of matter. Students often associated their body movements with colors before connecting the movements to more abstract representations of their activity, before finally connecting these abstractions to the states of matter. For example, students would first discover that moving fast around the room caused themselves to turn red on the screen, before concluding that spreading out and moving in faster speeds represented gas particles.

In the following transcript, students had yet to make observations on how to create blue (liquid). However, instead of suggesting a direct curricular goal such as, "let's make blue," Ms. Jones suggests trying something they had done before, to hold hands and walk in a circle. The decision to guide students towards playing in a circle was interesting because the shape she suggests does not have any scientific relevance—it doesn't represent any of the structures of solid, liquid, or gas particles. However, for the students it is a spontaneous, yet clear and understandable rule that Ms. Jones uses to guide inquiry.

1	Ms. Jones	One of the *things* that we did *before* to try and make the different colors (0.2)
2		was we all got in a circle and we moved in different ways. Could we try that?
3	Students	Yea::
4	Student 1	LET'S TRY TO MAKE A GINORMOUS CIRCLE AND SEE IF IF (0.1) if...one side is
5		blue and one side is red
6	Ms. Jones	Oh so you're looking at *where* we are in the space?
7	Student 2	EVERYBODY GET IN A CIRCLE!
8		((Students all gather in a circle))
9	Student 3	HOOK UP! HOLD EACH OTHER'S HANDS!

Figure 2. Students and Ms. Jones play in a circle

What made this example significant was not only that Ms. Jones didn't specify a science goal (line 1), but *how* the students took up her idea (line 4). In lines 3-5, we see how students are engaged in paidia play as they excitedly and fluidly build on her idea. We see evidence of this as students responded to Ms. Jones' by suggesting to make the circle more extreme and "ginormous", and by elaborating on her bid to focus on observing what happens next (Figure 2). This allowed Ms. Jones in line 6 to offer more guidance by re-phrasing and abstracting the students' idea of looking at spatial relations. Although we are focusing on the teacher's guidance, it is important to note that in lines 7-9, it is the students who take the agency to organize each other to carry out the play. After playing in the circle, a few students broke away and began to make further observations.

10	Student 1	And when we were spread out it was white and I think white was the *longest* and then
11		blue is the *shortest* because we were together and then the yellow is the shortest
12	Ms. Jones	So it goes white is long, blue is medium, and yellow is the shortest?
13	Student 4	What's red?
14	Ms. Jones	*Oooo* Student 4 wants to know how you make red

After walking in a circle, Student 1 (lines 10-11) observed and hypothesized the importance of distance when creating each color. While Student 1 was not completely accurate, it was the first time the students had made the conceptual connection between the distance between particles and different colors/states. Further, Ms. Jones was able to use her ideas to guide the class towards a crisp description of the role distance plays in making different colors and states of matter (line 12). The exchange ends, with the students specifying a goal for their next exploration--making red (line 13). This short exchange shows how the teacher's guiding moves of bringing spontaneous goals through paidia play can still benefit students with greater knowledge of the science content. Ms. Jones was able to guide student thinking to be more abstract and precise while still allowing the students the agency to set their own goals. The significance of this example is how Ms. Jones guided her students by bringing paidia play to life. She spontaneously pitched a seemingly unscientific goal to inspire her students to explore being particles together. Her guiding moves in paidia play led to students exploring the movements of a circle, and explore with whether these familiar sets of movements can help them create and embody states of matter. Here, teacher guided paidia play offers students opportunities to bring in these familiar everyday ideas to use as metaphors or starting points for investigating these concepts during scientific inquiry.

Case 2.

In our second case, we examine an example of student-initiated socio-dramatic play and how teacher guidance shaped the interactions for inquiry. While we consider socio-dramatic play to be a subset of paidia play, we make this distinction because of how students in this example move and interact according to the rules governed by a social role (or in this case, a student's exaggerated parody of a social role). Here, the students take on the role of an "old man" in order to establish both the goals and rules of their play and inquiry activity. Our analysis focuses on the discourse that unfolded while the teacher (Ms. Wilson) guides students' socio-dramatic play of being an old man towards the larger science learning goals. In the following transcript, the students were initially engaged in unstructured paidia play, with students running in circles and moving in exploratory ways to see how the simulation might change in response. Student 1 then proposes a goal for their play, and with the teacher's support, the activity begins to shift into more structured socio-dramatic play (line 1).

1	Student 1	Guys let's all be water! Guys-
2	Ms. Wilson	Oh (.) I kind of like Student 1's suggestion can you all try to be um (.)
3	Student 2	Liquid
4	Ms. Wilson	Yes (.) try to be liquid
5	Student 1	Student 3! Get clo- start moving like an old man
6	Ms. Wilson	So [look at the screen]
7	Student 4	[Old granny walking] [through!]
8	Student 1	[OH!] (.) we were just all
9	Student 4	Old granny moving through!
10	Student 1	OH! It's [doing it]
11	Student 3	[We're all-]
12	Student 4	Will you help me [please young lady]
13	Ms. Wilson	[Oh my gosh! (.) ((gasp))] (1) I have seen success
14	Student 4	[Young] lady (.) would you [please help me]
15	Ms. Wilson	[How] (.) [what am I] seeing to show that you are all
16		water what am I seeing [on the screen]

17	Student 4		[I need a cane]
18	Student 3	[Blue]	
19	Student 1	[It's] blue	

Figure 3. Students moving like "old people"

The role of being an old man is a clever way to communicate, embody, and self-regulate students' movements to move slowly, get close, and become liquid (Figure 3). The movement of an "old man" is parallel to moving like liquid particles in the mixed reality environment; in that liquid particles move slowly and closer together. As the students use the idea of the old man to slow their movement and arrange themselves together, the teacher guides the effects of the socio-dramatic play and tries to guide students' attention to the screen (line 6 & lines 15-16). In line 6 she says, "look at the screen" to guide students' attention towards the effects of their "old man" movements on the digital representation of particles. Since the screen (Figure 1) provides information on how students' movements create each state of matter, Ms. Wilson's guiding move to draw attention to the screen verifies that moving within the rules of an old man results in embodying liquid particles. In line 13, she states she has "seen success", and in line 15 she asks them to see what she sees on the screen. As a result, the students consistently look back to the screen to check for the creation of liquid while playing as old people. With his hand still clutching his back, Student 1 notices that they've successfully formed liquid particles with a shout of "Oh! It's doing it!" (line 10), and later notes that the particles have turned blue (line 19).

Within this guided socio-dramatic play space, the rules of embodying and pretending to be an old man were set by students as part of the imaginary situation. These rules and role of the old man were then guided by Ms. Wilson so that the socio-dramatic play would connect back to inquiry; making the scientific rules of being liquid visible. By calling attention to the technology, Ms. Wilson's guiding discourse helped organize the class to collectively work together in creating and verifying how to embody liquid particles.

Conclusions

The imagination of shrinking and pretending to be microscopic particles opened opportunities for students to enact, explore, and question the rules of matter in a variety of playful ways. We detailed in both of our examples how teachers and students engaged in play; where students maintained both a playful agency to their learning while still engaged in inquiry. In the first example, we see how Ms. Jones guided students' exploration of abstract scientific phenomena by spontaneously engaging her students in play. Here, the fluidity and emergent rules and goals of paidia play became tools for inquiry that Ms. Jones used to explore the significance of space and distance relevant to states of matter. In the second example, Ms. Wilson guided students' socio-dramatic play, where students collectively played the role of an old man in order to embody liquid particles. The significance of this example is that Ms. Wilson guided students' socio-dramatic play by connecting the embodied outcome of the imaginary roles and rules of the old man back to tools for inquiry. Across both examples, we saw how teachers led or responded to these varying kinds of play, guiding students towards the goals of inquiry while simultaneously valuing and building on students' agency and playful ideas. The teachers blend the exploratory benefits of children's play with the structure and content richness of formal classroom learning, creating a playful scientific inquiry space to encourage sensemaking.

Playful discourse for learning science

In both examples of teacher guided play, we primarily attend to the discourse, or talk that occurs as teachers guide and navigate students' interactions. These moments of teacher guided play reveal the unique opportunities for students to engage in alternative discourse and participation practices to help them learn and understand science. As a result, the discourse of participating and engaging in science is inherently different from traditional forms of learning, opening up what counts as learning and redefining how disciplinary discourse can look like in guided play. A commonality across the two types of guided play is how ideas and interactions that would typically be categorized as “unscientific” or “irrelevant” became powerful resources. Through guided play, students can draw from the known world around them to build an understanding of unobservable abstract scientific concepts in ways that blend ideas and behaviors from informal play with the concepts and questions of formal science.

Additionally, teachers in guided play took up students’ ideas and made them objects of inquiry for the whole class. In the second case, the concept of the old man was accepted by the teacher as a valid form of participating in classroom science learning. Here, the teacher’s response to students’ playful performance of being an old man was to guide and connect their movements back to the movements of liquid particles in the simulation. Similarly, in the first case, we saw how students built on the teacher’s suggestion to get into a circle by questioning spatial placement as a potential method of creating different states of matter. These ideas were a valued part of participating and engaging in scientific practices. In this way, guided play offers a way for students and teachers to navigate the sometimes uncomfortable territory of blending dominant school scripts with children’s play. Integrating students’ play into science learning allows students and teachers to have a more dialogic conversation about science, in which these unconventional, playful ideas are taken up as a valuable resource for doing science.

Refining Student Thinking through Computational Modeling

Hillary Swanson, Utah State University, hillary.swanson@usu.edu
Bruce Sherin, Northwestern University, bsherin@northwestern.edu
Uri Wilensky, Northwestern University, uri@northwestern.edu

Abstract: Scientists systematically refine their thinking through theory-building practices. Computational modeling is a key mode of theory building in the 21st century. This study investigates how engagement in the construction and refinement of computational models helps students refine their thinking. Specifically, it presents a microgenetic analysis of an episode during which a student refined their understanding of how disease spreads by building and refining a computational model of an Ebola epidemic. The analysis decomposes the episode into nine theory-building steps and locates the shifts in the student's thinking that occur in each step. It draws connections between these shifts and the theory building activity.

Introduction

In recent years there has been a shift, in science education, toward engaging students in epistemic practices (Ford & Foreman, 2006; Osborne, 2016). This builds on the perspective that students should construct scientific understanding through the kinds of knowledge-building practices scientists use to make sense of the world (Schwarz, Passmore, Reiser, 2017). Theory building is a central epistemic practice of science (Suppe, 1974). We define theory building as a family of practices through which scientists and students systematically refine theoretical knowledge artifacts, including explanations and models (Swanson, 2019). We further posit that as artifacts are refined, thinking is refined. This aligns with empirical work from sociology and cognitive psychology, which shows that scientists build knowledge by refining artifacts and existing ideas (Dunbar, 1997; Latour, 1999), and Einstein's (1936) notion that "the whole of science is nothing more than a refinement of everyday thinking."

Today, many scientists build theory by constructing computational models that, when run, produce outcomes that can be explored and compared with experimental findings (Weintrop et al., 2016; Foster, 2006). A number of research programs have designed and investigated ways of engaging students in theory building through computational modeling. diSessa (1995) used the Boxer computational modeling environment to help high school students articulate and refine their ideas about Newtonian dynamics. Sherin (2001) looked broadly at the possibility of using programming as a language for expressing simple physical ideas. Wilensky and colleagues have investigated student engagement in computational modeling of complex systems phenomena across domains using NetLogo (Wilensky, 1999; Wilensky & Reisman, 2006). More recently, Wilensky and colleagues have examined student model construction using NetTango (Horn, Baker, & Wilensky, 2020), a block-based interface to NetLogo. These studies examine the development of both scientific understanding and computational thinking that result from student engagement in computational modeling (Horn et al., 2014; Wagh & Wilensky, 2017).

Building on this tradition, the present research investigates how computational modeling helps students refine their thinking by driving them to refine a computational model. Specifically, we examine how one student refined her understanding of disease spread as she refined a computational model of the Ebola virus. We identify the smaller shifts in thinking that resulted from her engagement in constructing, testing, debugging, and making sense of the computational model.

Developing an understanding of the complex dynamics of disease spread is of particular relevance today, given the COVID-19 pandemic. At the writing of this paper, COVID-19 has infected approximately 48 million people worldwide and killed 1.2 million ("WHO Coronavirus Disease Dashboard," 2020). In addition to factors such as symptom-free carriers and a long incubation period, the success of the disease can also be attributed to the fact that it is just fatal enough to kill a percentage of those who are infected, but not fatal enough that those people become obviously sick and die before interacting with, and potentially infecting, many other people (Murray & Mearns, 2020). This quality of the coronavirus is at odds with commonsense conceptions about the fatality of a disease, which is that a disease that is very deadly to an individual must be very deadly to a population (Wilensky & Abrahamson, 2006).

This is a good example of what Wilensky and Resnick (1999) refer to as *levels slippage*. Levels slippage is a common error in novice reasoning about complex systems phenomena, whereby a characteristic at the individual level is mapped directly to the aggregate-level. In reasoning about disease, levels slippage occurs when a disease that is deadly to an individual is assumed to be deadly to a population. In reality, as our student learns, a disease that is very deadly to an individual may not be deadly to a population (without additional interacting factors), because it will sicken and kill its carriers before they have the opportunity to infect others. Understanding this complex dynamic between individual and aggregate levels is one of the key understandings that results from our focal student's engagement in computational modeling.

Theoretical foundations

Our analysis is founded on the basic premise of constructivism, which holds that new knowledge is built on the foundation of prior knowledge (Piaget, 1971). A constructivist epistemology known as knowledge-in-pieces (KiP) (diSessa, 1993), characterizes the process of knowledge construction as a refinement of a complex system of existing knowledge elements. The elements are cued variously for sensemaking, depending on a person's level of expertise. For the novice, the elements are loosely interconnected and employed in a manner that is highly context-dependent. For the expert, the elements are more reliably connected and cued more consistently in contexts where they are productive. Learning (or the movement from novice to expert) occurs through the reorganization and refinement of the networks of elements in the knowledge system. For this reason, the naïve knowledge system is viewed as a resource rich with potentially productive ideas for the construction of more expert knowledge networks (Smith, diSessa & Roschelle, 1994). This stands in contrast with the "misconceptions" perspective which regards naïve knowledge as incorrect knowledge structures that need to be removed and replaced (Chi, 2008).

KiP instruction focuses on eliciting students' ideas and refining those that are productive with respect to the context at hand. The construction of computational models provides an opportunity for students to articulate and refine their ideas. This aligns with constructionism (Papert, 1980), which argues that learning happens best through the construction of public artifacts, such as computational models. We posit that the systematic refinement of artifacts that is accomplished through scientific theory building, and in particular, computational modeling, affords and supports a refinement of thinking. This study seeks to understand how computational modeling supports learning. KiP views learning as the sum over smaller shifts, or refinements, in thinking over time. To understand how the construction and refinement of computational models supports refinement of thinking, we examine a case where learning occurred, looking for shifts in the student's thinking over time and connections between those shifts and the student's theory-building activity.

Methods

This paper presents the results of an analysis of data taken from a larger study. The goal of the larger study is to understand how to engage middle school students in different approaches to scientific theory building, including the construction of computational agent-based models. To lower the threshold for participation in computational modeling, we are designing block-based computational modeling microworlds using the NetTango platform (Horn and Wilensky, 2011). NetTango integrates the computational power of NetLogo (Wilensky, 1999) with the accessibility of block-based modeling languages. NetTango blocks are not a full programming language, but domain-specific blocks relevant to a domain that is modeled. Previously called *semantic blocks (*Wilkerson-Jerde & Wilensky, 2010) and now called *domain blocks* (Wagh, Cook-Whitt & Wilensky, 2017) the blocks are primitive elements of code that represent agents' actions and can be combined to model a specific phenomenon. We are designing domain-block libraries for simulating complex systems phenomena and studying how children use the blocks to build and refine computational models, and how their thinking is refined as a result. The present study seeks to characterize, at a fine grain-size, how theory building supports refinement of thinking and asks the question: *How does building and refining a computational model of the Ebola epidemic refine a student's thinking about the spread of disease?*

To address this question, we designed a NetTango modeling microworld that enables a user to build a model of the spread of disease. We tested the microworld with four students during individual 1.5-hour interviews. During the interviews, each student was seated at a desk that displayed a laptop featuring the computational modeling microworld. The student had full command of the laptop. The interviewer sat at the student's left and guided them through tasks and questions contained in a semi-structured interview protocol. The protocol began with an introduction to the study, its purpose, and the overall timeline of the interview. It then probed for students' background in computing and asked a few basic content-related questions (e.g., Do you know what the word epidemic means?). The protocol then moved on to introduce the student to the modeling microworld interface and specific blocks for programming procedures. It then prompted students to use the existing blocks to model diseases (e.g., Ebola). Data was collected during each interview in three forms: video, screen capture, and audio recordings.

The present report focuses on results from an interview with a student we call Sage. Sage was 13 years old and had just started the 8th grade at the local public middle school in her small Midwestern city. She had been introduced to block-based programming when her 7th grade science class participated in *Hour of Code*, an event hosted by schools all over the world to encourage students' interest in computing. The present report focuses on an excerpt from her exploration of the *Spread of Disease* modeling environment.

The *Spread of Disease* modeling environment is pictured below (Figure 1). The screenshot shows the modeling environment with a model that has been built and initialized. The black box to the left is the *world* which depicts the activity of the agents that are programmed to behave according to the rules specified by the model. The *setup* and *go* buttons are controlled by *setup* and *go* procedures (red blocks) that the user must drag from the block library (far right) into the modeling field (middle) and then define by connecting with blocks (purple, grey, and green) defined by specific commands, such as *move*, *if contact person*, and *infect*.

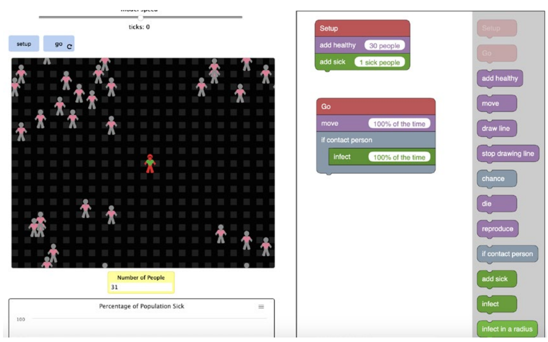

Figure 1. Screenshots of the *Spread of Disease* modeling microworld.

An audio recording of the interview with Sage was transcribed. Both screen capture (with audio recording) and transcript were analyzed to look for evidence of learning. A shift in thinking was identified during an activity in which she attempted to build a model of an Ebola epidemic. A microgenetic analysis (Siegler, 2007) of the episode was conducted to understand the smaller shifts through which her thinking was refined. The episode was ultimately divided into nine steps, each of which featured engagement in aspects of the theory-building process. These included building, testing, and debugging the computational model, and making sense of its simulated outcomes. Having created a temporal decomposition of the episode into these steps, the shifts in thinking that occurred during each were characterized and connected with the theory-building activities.

Findings

We present an episode from Sage's interview to illustrate how she refined her thinking as she refined her model. Ultimately, she developed a sense that a disease that was very deadly to an infected individual can actually be less deadly to a population. In this way, she may have ameliorated a common instance of levels slippage and developed a more sophisticated understanding of the complexity of the phenomenon.

Modeling the Spread of Ebola

Sage is seated at a desk in an office, the interviewer sits at her left. She is looking at a laptop screen on which the *Disease Spread* modeling microworld is open. She has been exploring the microworld for the last 25 minutes, trying out combinations of blocks and watching the resulting activity in the *world*. The interviewer wants to focus Sage on the task of modeling an epidemic and asks: "What if we were to try to make a model of the Ebola epidemic?" The steps below represent a temporal decomposition of Sage's trajectory through the modeling activity, highlighting her shifts in thinking.

Step 1: Building an Initial Model

Sage drags blocks into the programming field, specifying agent rules and constructing her initial model of how Ebola spreads through a population. To aid her design, she browses the internet for information on Ebola, including rates of transmission and death. Turning back to her model, she purposefully selects parameter values that align with what she has found.

> Sage: If sick die 50%, I'll have that, but maybe infect like 10% 'cause like I bet 10% of the time you're like, you accidentally like cough on someone and get their like your saliva in their mouth or something. And like that's, that's gross to think about it but um, infect, well yeah, infect like 10%. […] And then if you're sick, then you die. Let's say 50% 'cause that about ....

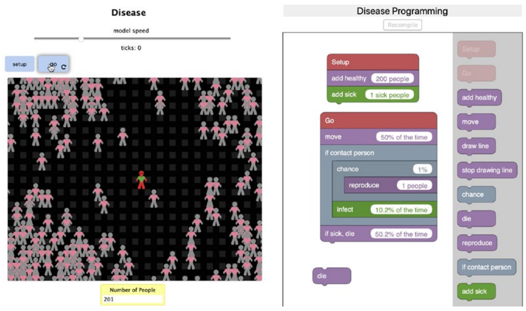

Figure 2. Sage's initial model of Ebola, before she presses "go."

As shown in Figure 2, Sage has set the model to initialize with 200 healthy people (grey bodies, pink hearts) and one sick person (red body with a green heart). With each tick of the clock, each person in the world will move with a 50% probability. If they contact another person, there is a 1% chance they will reproduce, and if they are sick, a 10% chance they will infect the person. If they are sick, there is a 50.2% chance they will die.

Step 2: Testing the Initial Model

Sage runs her model and observes as the single green person in the world disappears almost instantly.

Step 3: Making Sense of the Initial Model

Sage laughs, suggesting she is surprised by the outcome of the model-run. This is evidence that she expects a disease that is very deadly to infected individuals to be deadly to a population. She tries to understand what is happening at the agent level that would have caused the aggregate-level outcome, namely, why the sick person has disappeared, and why the disease did not spread and diminish the population.

Sage: What happened?!
Interviewer: And the number of, what's it look - what happened? Oh the number-
Sage: He died probably.
Interviewer: Oh yeah
Sage: 'Cause, 'cause it's like a 50, 50
Interviewer: Yeah. Yeah. Yeah. And he was already sick. So.

Sage reasons that the single infected person died quickly because they had a 50% chance of dying each tick of the clock.

Step 4: Debugging the Initial Model

Sage's first reaction is that there may indeed not be a way to program the model so that Ebola will spread as she expects. On second thought, she corrects herself, deciding that she could remedy the problem by adding more people.

> Sage: Hmm. Maybe, I don't, I don't think there really is a way to like, do, to do that, if that, because no, no, I could have more people. Um, I'm being ridiculous. Let's have 20 sick people, 21.

She attempts to debug the model by changing a parameter value, increasing the initial number of sick people in the world from 1 to 21. It appears she is testing an extreme value, thinking that it will surely help the disease to spread among the population.

Step 5: Testing the Revised Model

Sage runs her revised model to test the effect of her modified parameter and observes as the sick people (the 21 initially infected people and the people they infected) die within six ticks, leaving only healthy people, as before.

Sage: Then maybe they'll, Oh wait, no they all died.

Sage appears to be surprised by this result. This is evidence that the outcome of the model-run does not match her expectations. It suggests that she may expect a disease that is very deadly to infected individuals to be similarly deadly to a population.

Step 6: Making Sense of the Model Outcome

In an attempt to get Sage to make sense of the relationship between agent- and aggregate-level in this complex-systems phenomenon, the interviewer asks Sage what she thinks is happening.

Sage:	Um, epidemics are hard to start.
Interviewer:	Well, yeah. Well, when, what's hard to start about this one, do you think?
Sage:	Well, I think because, um, that it has a high fatality rate.
Interviewer:	Yeah
Sage:	And well maybe because the infectivity is so low, 'cause then if, um-

Sage appears to have drawn an important conclusion about complex-systems dynamics in the context of the spread of disease. This is that a high fatality rate will cause the carriers of a disease to die before they have a chance to spread it, making it in fact *less deadly* to the population. In arriving at this conclusion, Sage is beginning to construct a more accurate understanding of the connection between agent and aggregate levels. At the same time, she may be holding onto an intuition that the disease *should* be more deadly to the population, as she tries to think of another aspect of the model she could modify so that it produces the aggregate-level phenomenon she expects.

Step 7: Debugging the Model

In an attempt to debug the model and cause the disease to be more deadly to the population, Sage purposefully modifies a parameter setting, increasing the rate of infection.

Interviewer:	Do you want to change that and
Sage:	Yeah, let's, maybe people in this fictional city really like spitting in each other's mouth.
Interviewer:	OK
Sage:	Like maybe, maybe, maybe they're just like kissing everyone and that makes them more infectious.

Sage increases the probability of infection from 10.2% to 50.2% and recompiles the code.

Step 8: Testing the Revised Model

Sage runs her revised model to test the effect of her modified parameter. She observes as the sick people (the 21 initially infected people and the people they infected) die within 14 ticks, leaving only healthy people, as before. This outcome matches those of the previous runs, where the sick people die relatively quickly, leaving the world filled with only healthy people.

Sage:	Setup. Go. They're still all...

As before, Sage appears to be surprised by this outcome. Again, this suggests that she may expect a disease that is very deadly to infected individuals to be similarly deadly to a population.

Step 9. Making Sense of the Model Outcome

The interviewer engages Sage in making sense of the outcome of the model run. She wants Sage to consider what it would mean if her model were actually not flawed, but rather, a good approximation of a disease that is very deadly to individuals. In reality, the model is not a good approximation of Ebola, as that disease is very deadly to individuals yet has succeeded as an epidemic due to factors that are not representable by the block-based modeling infrastructure (e.g., healthy care-givers tending to their dying and deceased loved ones) (Hewlett & Hewlett, 2008).

Interviewer:	Wow. Is that what you expected to happen?
Sage:	No
Interviewer:	Well, what if you assume that your model is actually a good approximation of Ebola?
Sage:	Yeah
Interviewer:	What, what conclusion would you
Sage:	Well, like highly deadly diseases are hard to start epidemics, but when you do, they like really, really start 'cause, um, like, and like maybe, Hmm. I wish you could have like a, like there's, I don't know, like, 'cause like everyone's touching each other and they're like making people, let's take this out right now. Um, but, um- [...] they're reproducing and um, I don't know. It just, like, it, epidemics are hard to start. Um, even if you have people infecting each other like all the time, like they, like all of those people just died.

Sage compares the outcome of the model-run with her expectations and admits that the two do not align. She reflects on what she can learn from the model outcome and further expresses the notion that it is hard to get an epidemic to start when a disease is very deadly to an infected individual. It appears that she is clinging to an intuition that if such diseases do manage to spread, “they really start.” Still trying to find a way to build the model of Ebola so that it wipes out the population (aligning with what she has learned about the disease through the media) Sage removes the “reproduce” command from the “go” procedure.

Discussion

Analysis of this episode shows that Sage refined her understanding as she refined her model. She initially expected Ebola to spread and kill a larger percentage of the population. When her initial model did not produce her expected result, Sage modified parameter values (e.g., the initial number of sick people in the world and the probability of infection on contact) in an attempt to debug her model so the disease would spread. On testing her revised models, she found they still produced the same result. On reflection, she noted that “highly deadly diseases are hard to start epidemics” because their high fatality rates quickly wipe out the infected individuals who would otherwise spread them. In this way, by revising and testing her model, Sage refined her understanding. It is also apparent that her intuitions about disease are appealing and difficult to let go of, as evinced by her statement near the end of the activity “when you do [start an epidemic], they like really, really start.”

Her intuitions about Ebola are not unfounded, as she knows that the disease has indeed been an epidemic in Africa, and continues to be a risk. Ebola was able to become an epidemic despite its deadliness, however, because of other factors (e.g., family members caring for their dying and mourning their deceased) that were not represented in the model. Therefore, the important learning that occurred for Sage was a more nuanced understanding of the dynamics of disease spread as a complex-systems phenomenon, where the deadliness of a disease at the individual level does not directly correspond to the deadliness at the level of the population. In the activity that followed this episode, Sage constructed and refined a model of the flu. The activity helped to further refine her understanding, and she arrived at the conclusion “If [a disease] is like super, super fatal then it won't spread because like it will be super, super rare because like, um, then they let it, we'll just kill out all its carriers.”

The shift in Sage’s thinking over the course of the activity appears to be a correction of a classic case of levels slippage whereby a person determines that a phenomenon occurring at one level is directly caused by the same phenomenon at another level. In this case, a slippage between levels would be attributing the deadliness of a disease at the population level to the deadliness of a disease at the individual level. As Sage learns, however, just because a disease is deadly to an infected individual does not mean that it is deadly to a population.

Taking a step back and looking at what the analysis tells us about Sage’s learning, we see that refining the model helped Sage to refine her thinking. We postulate that all kinds of theory building engage students in refining artifacts that represent their knowledge, therefore helping them refine their thinking. It is important to acknowledge that this particular approach to theory building - building a *computational agent-based model* - afforded particular refinements in Sage’s thinking.

The fact that Sage was building a *computational* model meant that she could test her theory of how disease spread by clicking “go” and simulating what would happen in a world that was set up according to the initial conditions she selected, and behaved according to the rules she had specified. Had Sage not been able to test her revised models, she would not have seen that her modifications did not yield her intended results. She might have continued to think that a disease that was deadly to an individual was similarly deadly to a population, if one starts with enough sick people, or if the probability of infection is high enough. Testing out these agent-level modifications may have helped Sage see that they in fact had no significant impact on the phenomenon. Revising and testing her model helped her to see that regardless of the number of people initially sick or how infectious the disease was, if it was quite deadly to an individual, it would die out before it could spread, producing the opposite of what many people intuitively expect. The computational nature of her model supported refinement through *debugging*, whereby Sage was able to make small corrections to the model and test them, iteratively refining her model and her thinking.

The fact that the computational modeling microworld was *agent-based* meant that her model would be well-suited to simulating complex-systems phenomena. This, in turn, would help her more clearly see relationships between agent and aggregate levels, potentially clearing up any slippage between levels. Furthermore, the model was built using a block-based interface to the underlying computational agent-based modeling language, NetLogo. The blocks both afforded and constrained Sage's theory building. They afforded her entry into computational agent-based modeling, an activity which would otherwise have been inaccessible without some training in the language. It constrained her theory building because there were only particular commands available. Sage noted a number of times, during the interview, that she wished there had been ways of accomplishing something that was not currently afforded by the block-based modeling infrastructure (e.g., making the person infect a certain number of people before they died).

In addition to making a contribution to work concerned with engaging students in science practices, this work makes an empirical contribution to literature on conceptual change, by offering a microgenetic account of how one student's thinking changed as a result of engagement in theory building. Microgenetic accounts of learning are few and necessary for understanding the finer mechanics of learning (diSessa, 2014). Finally, our work makes a contribution by demonstrating an important connection between knowledge-in-pieces and constructionism: that through the refinement of a physical and publicly shareable artifact, students can refine their thinking.

Computational Thinking through Body and Ego Syntonicity: Young Children's Embodied Sense-Making Using A Programming Toy

X. Christine Wang, Virginia J. Flood, Alice Cady
wangxc@buffalo.edu, vflood@buffalo.edu, alicecad@buffalo.edu
Graduate School of Education, State University of New York at Buffalo, USA

Abstract: Papert's concept of body syntonicity (how an experience aligns with learners' sense and knowledge about their own bodies) has been embraced by learning scientists; however, his notion of ego syntonicity (how an experience aligns with children's sense of self as people with intentions, goals, desires, likes/dislikes) is less discussed. We argue body syntonicity (BS) and ego syntonicity (ES) are both critical dimensions for understanding how young children learn abstract concepts and skills as part of embodied computational thinking (CT) with tangible programming toys. Using multimodal interactional analysis, we demonstrate how a preschooler (aged 4) used both physical enactment (BS) and intense emotional involvement (ES) with precisely coordinated response cries (e.g., collaborative cheering, gasping) to make sense of how a continuous spatial route can be decomposed into discrete programmable steps. We discuss implications for learning sciences at large and for supporting young children's learning of decomposition and other CT practices.

Introduction

Viewed as "the new literacy of the 21st century," computational thinking (CT) is the systematic analysis, exploration, and testing of solutions to open-ended and often complex problems (Wing, 2011). In addition to its direct application for computer science or programming, CT is also essential to a broad range of planning, critical thinking, and problem-solving situations in other domains such as reading, writing, and arithmetic (Wing, 2006). Given its importance, there are burgeoning, albeit, limited efforts to explore and promote CT in early childhood (ages 0-8; Çetin & Demircan, 2018; Jung & Won, 2018). However, the majority of these studies focus on the feasibility of introducing CT to young children or effectiveness of such efforts (Wang & Choi, under review). As a result, we still have limited understanding of the *processes and mechanisms* through which young children acquire abstract CT concepts and practices.

To address this gap, we investigate how young children (ages 3-4) can participate in the CT practice of *decomposition,* and we adapt Papert's (1980) concepts of body syntonicity and ego syntonicity to make sense of this process. As one of the foundational components of CT, decomposition is defined as breaking down a complex problem into smaller or more manageable parts (Shute et al., 2017; Wing, 2006). For example, in this paper, the participating children were engaged in decomposing a continuous spatial route (moving from "Start" to "Home" and avoiding an obstacle in the path) into discrete programmable steps (attaching different body segments with commands such as go straight, turn left, and turn right) using a programming toy. Decomposition is an important research focus for understanding young children's CT thinking because dealing with different parts of a complex problem all at once may be especially difficult for young children considering their still limited although fast developing memory capacity.

Theoretical framework and relevant literature

Papert (1980) defines body syntonicity as aligning learning tools and experiences with learners' "sense and knowledge about their own bodies" (p. 63), while "ego syntonicity" as aligning learning tools and experiences with learners' "sense of self as people with intentions, goals, desires, likes and dislikes" (p. 63). Embracing Papert's idea that model of learning should "draw on our own behaviors *(i.e. sense of self)*, our own bodies." (p.64), we argue both body syntonicity (BS) and ego syntonicity (ES) are critical dimensions for understanding how young children learn abstract concepts and skills. Both BS and ES can be considered forms of embodied understanding that children have access to.

In the larger learning sciences community, there is broad support for the notion that the body can serve as a key resource for programming and engaging in CT practices. It has been exemplified by the early work of Papert with Turtle Geometry (1980) and the more recent Maker Movement that emphasizes making learning visible and tangible by designing and physically making robotics, textiles, videogames, etc. (Peppler, Halverson, & Kafai, 2016). There are also concerted research efforts to understand how body syntonicity supports and scaffolds learning. For example, Fadjo et al. (2009) found that elementary school children instructed to use their bodies to act out Scratch programming statements outperform those who merely imagine the statements.

Capitalizing on body syntonicity, Berland et al. (2011) developed IPRO "Programming Standing Up," a mobile programming environment where learners use their bodies to simulate and program a robot to play soccer. In this embodied educational programming environment, students overcome impasses by physically acting out their programs and collaboratively debugging them in ways that are not possible with traditional "seated" programming environments. However, while these studies provide useful insights on how body can be used as *physical problem-solving tool*; they have not explored the role of ego syntonicity in students' *affective embodied sense-making.*

There is growing recognition and interest in the broad role of ego syntonicity (ES) plays in the learning sciences. For example, some researchers have foregrounded students' science identity and sense of belonging in the community of practice, and examined how they are developed and how they shape and support science learning (e.g., Kim, Sinatra & Seyranian, 2018; Barton & Tan, 2010; Varelas, Martin & Kane, 2012). Other researchers have zoomed in on how embodied emotion can be a resource for sense-making at a micro moment-to-moment level. In science education, a number of scholars have demonstrated that students' intense affective experiences (e.g., vexation, wonder) can play a central role in driving their engagement and motivation to solve difficult problems both alone and together (e.g., Engle & Conant, 2002; Jaber & Hammer, 2016). In mathematics, Nemirovsky (2011) has demonstrated that episodic feelings (e.g., surprise, enthusiasm, esthetic appreciation) can help learners narratively make sense of and connect together distinct learning experiences. Notably, Nemirovsky argues that embodied experiences of learning cannot be fully understood without attending to their entangled emotional and affective character. Drawing on these studies collectively, we adopt the position that moment-to-moment emotional responses and experiences are likely fundamental to the ways that leaners make sense of STEM practices and their sense of self in relation to the learning tasks and subject areas at hand (i.e., identity). Currently, research on children's emotional engagement and experiences in CT learning (ES at a micro level) or how learner identity (ES at a meso or macro level) is related to CT learning is sorely lacking.

Addressing this gap, our study explores the role of both body syntonicity and ego syntonicity in young children's CT learning. Specifically, we ask the following research question: how can preschoolers use both physical enactment (BS) and intense emotional involvement (ES) to make sense of decomposition in a teacher-guided group coding session? We focus on a classroom's use of a tangible programming toy, and how a focal child first physically enacts a continuous spatial route but misses some steps, and later is able to decompose it into accurate, discrete programmable steps, after he collaboratively narrates the route and engages in precisely coordinated response cries (e.g., collaborative cheering, gasping) with his group. Response cries are "exclamatory interjections that are not full-fledged words" (Goffman, 1978, p. 800) and are used to display emotion in interaction (For example, like surprise (e.g., Oh!) or revulsion (e.g., Ew!)). Response cries can also be used as interactional resources for drawing joint attention to objects and processes (Streeck et al., 2011). In this study, we show how coordinated response cries help the children perceive and recognize a continuous spatial trajectory in terms of discrete programmable steps in order to navigate the tangible programming toy (i.e., in the process of decomposition).

Significance

Understanding the process of how children use decomposition to solve spatial problems can have important implications. Theoretically, by adopting both body syntonicity (BS) and ego syntonicity (ES), our study brings the affective embodied dimension of learning to bear along with the physical body. Thus, our study embraces learner-centered philosophy in its fullest sense. Practically, we argue that understanding how to support both BS and ES may help teachers and parents strengthen young children's learning of CT concepts and practices by leveraging children's knowledge and sense of their body (both emotionally and physically) and motivating them with connections to their own desires and emotions.

Methods

Our present study emerged as part of a larger investigation examining young children's CT learning with a commercially available programming toy at a University-affiliated preschool in the United States. Children worked with Fisher-Price's Think and Learn Code-a-pillar (Code-a-pillar for short) (https://www.youtube.com/watch?v=3d4zXauy6EM) in small groups once or twice a week (average 15 minutes per session) for over 12 weeks. Twenty-two children and two teachers participated in the study. As shown in Figure 1, the Code-a-pillar is shaped like a caterpillar but has interchangeable body segments that program the caterpillar to move and behave in multiple ways. Each body segment represents a different command (e.g., turn right, turn left, go straight, play music). In a purposefully-designed introductory session, children named the Code-a-pillar 'Rapunzel' through a process of brainstorming and voting, decorated a house (a box) for Rapunzel, and learned rules for taking care of her. Each week, children engaged in new programming challenges that often-involved imaginative stories about Rapunzel and required "helping" her navigate to desired locations in the room by programming her. With the teacher's guidance, children engaged in various forms of CT thinking and were encouraged to empathize with the caterpillar's goals (e.g., going home, escaping a toy wasteland). All sessions were video recorded, creating a corpus of about 15 hours.

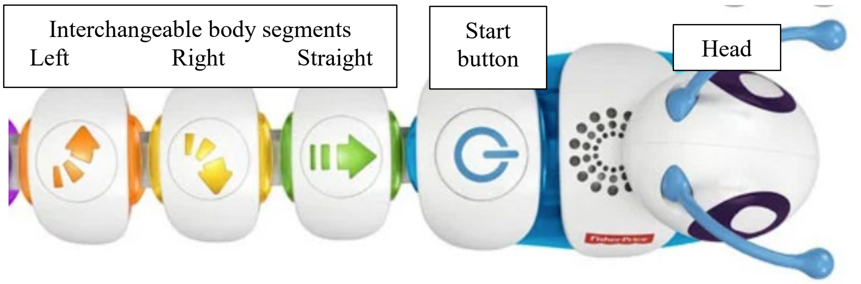

Figure 1. Code-a-pillar (named "Rapunzel" by the children in the present study)

We selected the case we present here because it illustrates how ego syntonicity and body syntonicity can be tightly interwoven as part of children's computational thinking. The session of interest occurred during the ninth week as Mr. Samuel worked with three children, David, Ned, and Peter (all names are pseudonyms) (see a screenshot of the video recorded session in Figure 2). David (aged 4) was Korean-American and an English language learner, Peter (aged 3) and Ned (aged 4) were Caucasians. Mr. Samuel, African American, had been teaching at the pre-school for 7 years.

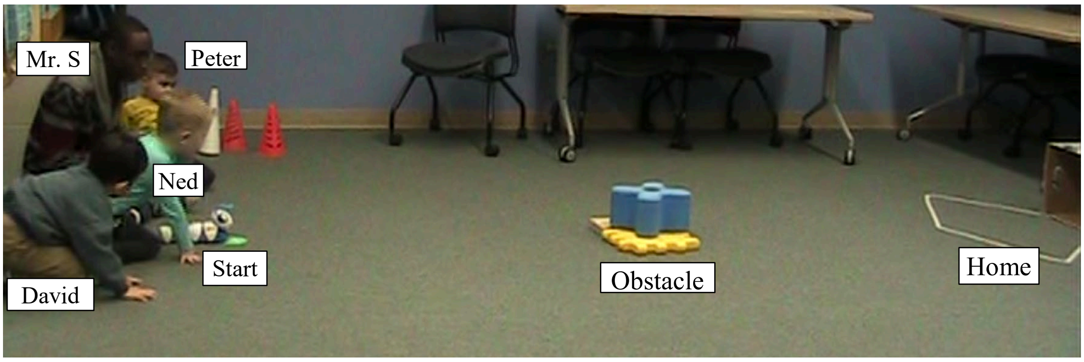

Figure 2. Mr. Samuel and the children in the focal session

Our analysis highlights how Ned's description of the route became more sophisticated over the episode, and the role that body and ego syntonicity played in this process. To understand the progression of Ned's idea about the route Rapunzel should take, we conducted a multimodal analysis of the group's interactions (Jordan & Henderson, 1995; Streeck et al., 2011) during the session. We transcribed participants' speech, facial expressions, vocalizations (e.g., response cries), body movements, and gestures. We also treated Rapunzel as a participant, and her actions were also transcribed. Our close attention to detail revealed the refinement in Ned's understanding of the Code-a-pillar's steps before and after a collaborative narration of its route. Our careful analysis of intense displays of emotional involvement during the collaborative narration revealed how these displays punctuated the Code-a-Pillar's trajectory in space to make it perceivable as a discrete sequence of steps (a form of decomposition).

Findings and discussion

During the session of interest, Mr. Samuel presented the children with a new task: Help Rapunzel, the Code-a-pillar, navigate around an obstacle (a pile of foam objects that the children imaginatively decided to be a snow mountain with a popular cartoon villain on top) and reach her home (the decorated cardboard box) on the other side of the room, about six feet away (see Figure 2). Solving the problem of getting Rapunzel from "Start" to "Home" around the obstacle required the children to break a relatively complicated continuous spatial route down into a sequence of discreet programmable steps using the commands they had available: body segments that make the Code-a-pillar (1) turn right, (2) turn left, or (3) go straight.

To program this route, the children must make sense of and comprehend (1) the continuous trajectory through space (the path or route) that will achieve the goal of getting Rapunzel from Start to Home and (2) how to organize and translate this path into a language the Code-a-pillar understands: a sequential series of commands (turn left, turn right, go straight) dictated by the segments that must be attached to her body. Translating the spatial route into a sequence of steps requires engaging in the important CT practice of *decomposition*. In addition, the children also need to engage in *debugging* to identify and rectify errors in the series of commands they choose (another important CT practice). There are two viable options: passing to the left of the obstacle or passing to the right. If passing to the left, the series of steps could be (a) straight, (b) left turn, (c) right turn, (d) straight, (e) straight, (f) right turn. This is the solution that the group eventually settled on.

In their first attempt, the children only attached two movement segments (one straight and one left turn) to Rapunzel, and as a result, Rapunzel stopped in front of the obstacle as shown in the screenshot (Figure 4). After this failed trial, Mr. Samuel asked them to stop and think.

In response, Ned mapped out a proposed trajectory and series of steps for Rapunzel (Figure 3). Using his finger on the floor to trace a route, Ned crawled from Start to Finish around the obstacle to the left. As he traced and crawled, he named the series of commands he thought would achieve this route (see Table 1)—straight (02), straight (04), left turn (05), right turn (08), and straight (12). The screenshot in Figure 4 captures the next-to-the last step (line 12) when he almost reached Home and the diagram in Figure 3 shows where each of his speech/action lines occurred as he mapped out the route.

By physically enacting (both moving the finger on the floor and crawling forward) Rapunzel's route, Ned was using his body to both plan the path and break the path down into steps. Interestingly, although his audience was at Start, Ned faced Home and crawled with his back toward them the whole time as if he was moving as Rapunzel would. He both simultaneously adopted a *character view point* with his body (facing the direction Rapunzel faced, moving through the space as if he was Rapunzel) and an *observer view point* (using just his finger to trace the route Rapunzel would take). Crowder (1996) has demonstrated that when students adopt a character view point to use their bodies to represent ideas, they are often still in the process of making sense of scientific explanations, and when they adopt observer view-points (such as pointing), they are often relaying already thought-through responses. Here, we argue Ned's blended view point suggests he was both (1) using his body to think through the route, a form of body syntonicity, while (2) simultaneously attempting to illustrate this route for the others by using his finger.

Table 1: Ned plans out Rapunzel's route on the floor

	Ned's Speech	Ned's Action/Gesture
01	I think, we have to go	
02	straaaight, ((pause))	((Drags right finger forward across the floor toward the obstacle as he crawls forward.))
03	and then	((Pauses))
04	straaaight, ((pause))	((Sweeps finger and entire arm backward. Pauses))
05	turn. ((pause))	((Sweeps right finger forward across the floor toward the obstacle as he crawls forward.))
06	And then ((pause))	((Drags right finger slowly to the left. Pauses, then draws a left turning path .))
07	then ((pause))	((Slight pause. Traces finger on floor to go straight forward.))
08	It turns	((Traces to the right toward the home box while crawling forward))
09	This way	((Continues forward tracing a straight line with his finger as he crawls.))
10	and	((Veers to the right with his finger, around the obstacle.))
11	then	((Readjusts, moves his finger and body path straight))
12	straight	((Continues across the floor tracing a straight path into the home box.))

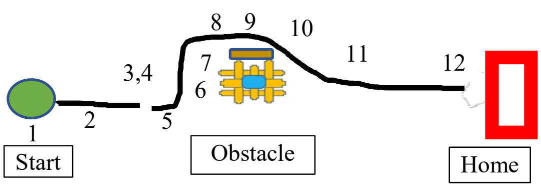

Figure 3. Diagram of Ned's route for Rapunzel

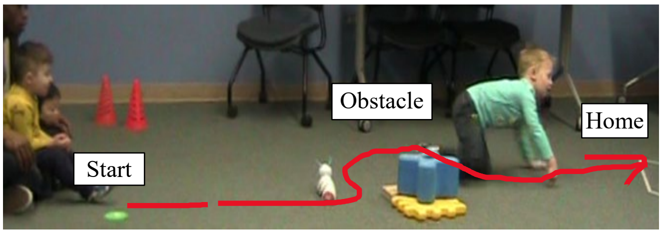

Figure 4. Screenshot of Ned planing Rapunzel's route

Although the path Ned embodied and traced could achieve the goal, he had not fully decomposed it into programmable steps that would work, particularly towards the end of the path. He would need a second right turn to properly line Rapunzel up with her "Home" (although he does embody the continuous curve of the path to get her there) and he also was missing an additional straight command to get her far enough to make it all the way home (although again he traced it). His proposed programming steps would result in Rapunzel ending up short about 2-3 feet and too far to the left of the goal.

Based on Ned's proposed route and steps, the group programmed Rapunzel by attaching five movement segments (a. straight, b. left, c. right, d. straight, e. straight). But Rapunzel stopped short to the left outside of her home. Mr. Samuel took another student, Peter, by the hand, and together they found the solution by walking the final step for Rapunzel. As a result, the group decided that they needed one last piece (f. right turn). A third student, David, attached the final piece and pressed "start."

Together, the Mr. Samuel and the group of children observed Rapunzel's "run" to see what would happen with this new revision. However, the group did not just passively watch Rapunzel progress, instead engaged in an emotionally charged collaborative narration of each step along the way. The diagram in Figure 5 shows how participants' vocalization and action lines (01-22) correspond to Rapunzel's movement (a-f) and Table 2 also uses alternative background colors (red and blue) to correspond to the color of Rapunzel route in the diagram.

Table 2: The group observes Rapunzel's home run

	Participants' Speech and Vocalization	Participants' Action	Rapunzel's Movement
01	Mr. S: Maybe some popcorn she'll have	((Children giggle))	Rapunzel starts moving forward (a)
02	when she gets home. I don't [know.		
03	Children: [OOHhhhh]	((Children lean forward))	Rapunzel continues forward (a)
04	Mr. S: Now, okaaay, now	((N puts hands over mouth))	Rapunzel begins left turn (b)
05	Mr. S: she turnnns		Rapunzel continues turning left (b)
06	Mr. S: Peter, watch, look	((Mr. S points at Rapunzel))	Rapunzel begins turning right (c)
07	Mr. S: And then a riiight turn[nnnnn]		Rapunzel continues turning right (c)
08	D&P&N: [nnnnn]		
09	Mr. S: And then a ST[raaaaaight]		Rapunzel straightens out (d)
10	D&P&N: [Straaaight]		Rapunzel moves forward (d)
11	D: anoder stre[eeeeeee]		
12	Mr. S: And then another stra[aaaight]	((N puts his hands on his mouth and sits up))	Rapunzel starts the next forward command (e)
13	D: [aaNAAHaha!	((D crawls forward))	
14	N: [Nnnnnnnnnn	((N sits further up on knees))	Rapunzel continues straight (e)
15	Mr. S: And THEN	((N inches forward))	
16	(pause)		
17	P: Mmmm[mmmmmmmmmmm		Rapunzel finishes the forward (e)
18	D: [RAAAAIGHTT]		
19	Mr. S: [AND THEN A T]URRN Aaaaaaaah]		Rapunzel begins to turn right (f)
20	Children: [mmmmmmmmmmmmmmmmmmm]		Rapunzel enters the target zone, continuing to turn right (f)
21		((Mr. S throws his arms in the air and then starts clapping))	Rapunzel stops
22	D: Yeah!	((Mr. S, D, P, and N clap, and children start to dance))	

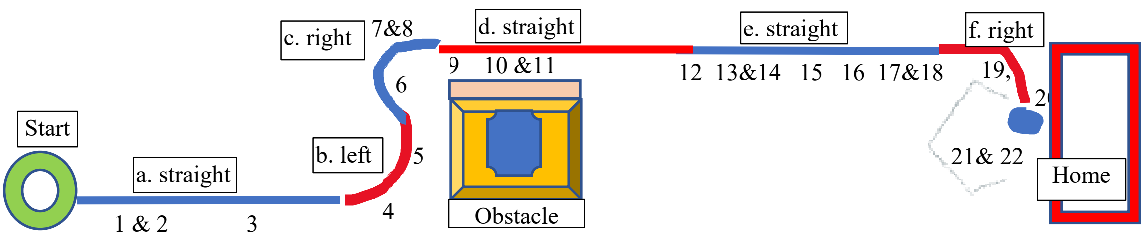

Figure 5. Diagram of Rapunzel's home run

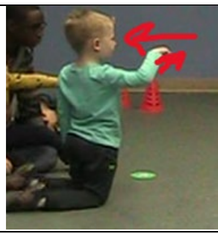
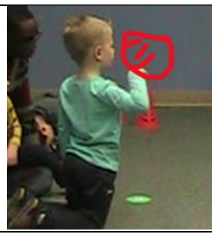
As the run occurred, Mr. Samuel acted like a sports announcer by setting up the scene (01) and detailing Rapunzel's each step (05, 07, 09, 12, 19). The children were intensely engaged and their actions showed intense focus: leaning or inching forward (03, 15), sitting up straight (12, 14), and crawling forward (13), and holding back vocalization by covering their mouth (04, 12) at each consequential step. In addition, the group's collective response cries were precisely coordinated to respond to Rapunzel's movement. Along the way, they gasped, laughed, used elongated sounds, and engaged in playful screams and shrieks. For example, for Rapunzel's fifth movement (e. straight), the children started with intense focus (Ned sitting up with hands covering his moth in 12 and David crawling forward in 13) and cried out in excited anticipation (David uttering intensely excited noises, nearly screaming, in 13). As Rapunzel continued going straight, the children audibly lowered the volume of their response cries, e.g., Ned sat further straight and uttered "Nnnnnn" displaying nervousness (14). Finally, when Rapunzel completed this turn (e. straight), children let out louder joyful shrieks to release the tension until her next new turn started again. To coordinate their collective response cries with Rapunzel's movements and Mr. Samuel's narration, the children had to attune their attention to each place where Rapunzel's continuous spatial trajectory was broken down into the discrete steps they had programmed for her. The range of strong emotions that they performed together showed that they were deeply invested in Rapunzel's success. Overall, the children's intense embodied emotional involvement with the toy's route and programmed steps constitutes a form of ego syntonicity that appears to help them recognize how the continuous spatial trajectory was decomposed into discrete steps.

After this final run, and the body syntonicity (Table 1) and ego syntonicity (Table 2) experiences discussed above, Ned demonstrated a more sophisticated understanding of the decomposition of the route by accurately describing the steps needed to bring Rapunzel to her home (see Table 3). Ned's answer now contained the missing steps he omitted before (e, and f) as he successfully decomposed the whole route into programmable steps. Instead of describing the path through space (which was part of his first explanation in Table 1), he now only seemed to be recounting a list of the discrete programming steps. Each statement corresponded to Rapunzel's segmented movements. There were also less pauses and disfluencies (Crowder, 1996) in his recount compared to his initial planning, and he was more fluent as he described the entire route, suggesting that he was no longer thinking it through how to map the continuous trajectory to the steps, but could just see it as a list of steps. In addition, Ned's gestures were no-longer in character view point (he was only using his hand, and not his whole body), which also suggests he had made sense of the route, and was narrating what he already understood (Crowder, 1996). This is a stark contrast to the first attempt at decomposition, when he was working out the turns, as he went, with his body. Further evidence of Ned's improved competency in regards to decomposition is illustrated by the absence of gesture toward the end of his explanation. Ned did not completely gesture the last two-three steps and relied more on speech to complete the idea.

<u>Table 3: Ned recounts Rapunzel's route</u>

	Ned's Speech	Ned's Gesture
01	We had ta straight	((Moves right arm straight out, pointing finger straight.))
02	turn	((Moves right arm toward his left.))
03		((Makes a slight point forward.))
04	turn	((Extends arm back to the right and forward.))
05	straight	((Retracts arm closer to body.))
06	straight	((Slightly moves finger.))
07	and then- and then- turn.	((Moves finger slightly three times.))

01 & 02	03	04	05	07
				




Throughout Ned's participation, character view point and gestures served as an important stepping stone to developing a more sophisticated computational way of analyzing a situation, and they eventually give way into a more sophisticated description of the decomposition in words. This aligns well others' findings in math and science that that gestures can help reify and objectify abstract patterns (e.g., Radford, 2003) and play an important role in developing technical language (e.g., Roth & Lawless, 2002). However, we argue that Ned's experience is irreducible to just physical bodily activity (in this case body syntonicity). Instead, our study shows the equally important role of intense emotional engagement in learning (ego syntonicity). Collective response cries drew the children's attention to the relationship between the spatial trajectory and discrete programmable steps, and thus likely deepened Ned's understanding of the decomposition in this case.

Conclusion

As an exploratory study, we used a small group of preschoolers' embodied CT learning to illustrate how body syntonicity (BS) and ego syntonicity (ES) can both support children's' sense making of the CT practice of decomposition. While the connection between Ned's BS experience and his learning of these CT concepts and practices is well supported by other embodiment research (e.g., Crowder, 1996; Radford, 2003; Roth & Lawless, 2002), our study highlights the equally important role of ES in children's learning. Although we only focus on the role that intense emotional engagement plays (ES at a moment-to-moment micro level) through the focal session in the findings, we have noted myriads ways the children's ES are being supported. For example, the Code-a-pillar design (life-like features and actions), the curriculum design (naming Rapunzel in the introductory session – see Methods for detail), the teacher's guidance (designing tasks related to Rapunzel's needs), and children's collaboration all contributed to ES at a broader level. Overall, we argue that leaving out ES would result in an incomplete picture of Ned's embodied sense making of the decomposition of the route. Like Papert, we argue that the emotional body and the physical body both play a key role in learning to program. Therefore, we strongly advocate learning sciences communities to pay attention to both BS and ES in their examination of learning processes as well as their design of learning experiences and tools. In practice, teachers and caregivers should consider allowing and supporting children to leverage their knowledge of their body, their sense of self, and their emotions in making sense of CT concepts and practices.

By revisiting *both* of Papert's classic notions of the embodied dimensions of programming – body and ego syntonicity – and bringing them to bear in the case of young children's experiences with a new, tangible programming toy, we embody this year's conference theme by reflecting the past and embracing the future. In particular, our findings lend additional support to Papert's assertions that ego syntonicity plays an important role in how children make sense of tangible programming toys, and warrants further investigation and attention in the design of future learning experience as well as tangible programming toys for young children.

Moving forward, we are planning to extend this research in several directions. First, we will investigate the role body and ego syntonicity plays in supporting students' engagement in other aspects of CT learning. Our data already hinted at some potential effects of ES on debugging, another key CT practice. We also believe ES is particularly well suited to foster desired CT attitudes and perspectives (e.g., collaboration and communication, perseverance, productive failures, tinkering spirit) because its explicitly connects to one's sense of self. Second, we plan to further unpack the social dimensions (e.g., peer collaboration, and teacher scaffolding) of integrating BS and ES to better understand how "'making sense' is a social process" (Bruner & Haste, 1987, p. 1). Third, we will examine the affordances and constraints of tangible programming toys such as Code-a-pillar for young children's BS/ES in their sense making of CT. For example, we have noticed that Code-a-pillar's life-like features lend themselves well for children to project and to align with their own desires, needs and emotions. Code-a-pillar's interchangeable body segments can be attached and detached, which also provides an intuitive way to decompose a continuous route into discrete steps. Finally, we will also explore potential connections between the moment-to-moment emotional and embodied experiences in CT learning (i.e. BS and ES at a micro-level) and the broader macroscale processes of developing learner identities related to computer science (BS and ES at a meso or macro level). Challenging the Cartesian dualism of emotion (body) and knowledge (mind), we believe this integrated BS/ES-based approach to understanding and supporting CT learning may be especially valuable for helping make CT more inclusive for children from non-dominant communities with non-Western epistemologies.

Endnote: Transcript conventions

(1) Brackets [] show overlapping speech or vocalization that occurs at the same time.
(2) ((Double parentheses)) denote nonverbal activities and embodied actions such as gesture.
(3) CAPITALS denote loud speech.
(4) Nnnnnnnnnn extended letters show elongated sounds and cries.

Model-Based Reasoning with Immersive VR Simulations: Patterns of Use Grounded in Time and 3D Space

Abstract: This paper explores the affordances of virtual reality (VR) simulations for model-based reasoning. Thirty-four undergraduate students engaged with simulated scientific models in head-mount displays in either a seated or standing position. To examine how simulation and learning activity supported model-based reasoning, we coded facilitator-participant interactions using the Structure-Behavior-Function framework and inductively analyzed the exchanges for key themes relating to *how* students interrogated the model. Findings showed that students examined the model's function most frequently, followed by structure then behavior. They spontaneously observed the model's structural components, which at times led to more in-depth student-driven inquiries. Students attended to components' behavior in the form of immediate situated feedback while demonstrating their conceptual understanding. Students compared and contrasted the multiple simulated states to elaborate on the model's function. However, mental workload and prior knowledge were mediating factors. Lastly, predictions about the model's function drew upon structure and behavior 'levels' in student reasoning.

Understanding dynamic systems with simulations

It is well understood that different external representational forms can influence how people think about a phenomenon (Wilkerson-Jerde et al., 2015). For instance, dynamic visualizations (or animations) of molecular processes and mechanisms depict change over time particularly well, engaging learners with temporal dimensions of phenomena (Tversky et al., 2002). On the other hand, agent-based models (Wilensky & Reisman, 2006) afford learners to explore underlying rule-sets of a complex phenomenon through experimentation (Levy & Wilensky, 2009). A wealth of research in the learning sciences, representing well over two decades of effort, has examined in-depth how computational tools can engage learners with complex concepts in a multitude of scientific domains (for a summary, see Yoon et al., 2018). Nevertheless, certain scientific concepts remain challenging for learners to learn with deep understanding.

Complex phenomena with multilevel organization, interconnections, and emergent properties that are invisible, dynamic, and interdependent are particularly prone to misconceptions (Chi et al., 2012; Hmelo-Silver et al., 2007). According to research comparing novice and expert understanding of complex systems using the Structure-Behavior-Function (SBF) framework, Hmelo-Silver and colleagues (2000) found that novices tended to focus on visible structures rather than the behaviors of components or functioning of the overall system. Meanwhile, Chi and colleagues (2005; 2012) hypothesized that novice learners misinterpret the emergent and dynamic properties of scientific models as sequential processes because they lack the schema required to interpret non-sequential processes. Authors suggest that an emergent schema may be taught to students with instructional material that incorporates dynamic computer simulations. The increasing availability of immersive virtual reality (VR) offers promise as a form factor for "experiencing" typically unobservable phenomena, including those at non-tactile scales that students found challenging to perceive (Tretter et al., 2006). VR simulations can also be designed to include properties of dynamic visualizations and computational models. However, we are just beginning to understand how VR simulations can help learners develop appropriate schemas while interrogating complex systems models.

Embodied simulation environments

Based on the embodied cognition theory, how we create and recall mental constructs is influenced by the way we perceive our surroundings and move our bodies (Barsalou, 2008; Shapiro, 2014). Some theorists suggest that "activity in sensorimotor cortices causes conceptual activity (because they are substantially the same) and conceptual activity causes sensorimotor activity (for the same reason)" (Johnson-Glenberg et al., 2015, p. 181). Recent research examining the impact of experimenting with agent-based computational simulations on student explanations (of gold nanoparticles) found that the desktop simulations offer an embodied learning experience (Lai et al., 2018). Viewing videos of dynamic visualizations, however, did not produce evidence of an embodied experience. Authors posit that interacting with the simulation helped students construct new schema about nanoscale target structures, which they incorporated into mental simulations and called upon when asked to explain their understanding. Computer simulations are believed to present certain advantages over traditional abstract representations (e.g., seen in textbook diagrams) by providing “a perceptual grounding for concepts that might otherwise be too abstract to readily comprehend” (Goldstone & Son, 2005, p. 72). Interestingly, prior research suggests that agent-based computational modeling environments present unique perspective-taking challenges for learners (Sengupta & Wilensky, 2009) — which point to a need for additional research in this area. Unlike conventional desktop simulations, VR simulations allow users to move freely and interact with objects, opening up opportunities to ground abstract concepts into concrete manipulatable representations for the learner.

Early explorations of VR simulations, such as the ScienceSpace project by Dede and colleagues, show promise for supporting students to learn complex scientific concepts of mechanics, electromagnetism, and chemistry (Dede et al., 1996). More recent VR designs for addressing scientific understanding focus on storytelling approaches (Ba et al., 2019; Zhang et al., 2019). This paper examines virtual reality as a form factor for supporting model-based understandings and makes the case that VR simulations *can be designed* for learners to construct new schema relating to the structure, behavior, and function of complex systems. By examining the affordances of an immersive VR simulation to support university students as they explore a complex genetic regulation model, this study considers virtual reality simulations as an external representational form for thinking about complex phenomena.

In our previous work, we conducted a study that examines the use of a VR simulation and learning outcomes with students from a microbiology course (Lui et al., 2020). We compared students’ conceptual understanding between students who experienced a VR simulation in either a sitting down or standing up position (to examine gross motor effects), along with a group of students that did not experience the simulation. We found that students who engaged with the VR simulation performed significantly better on a concept inventory test than students who did not. Our findings, which examine the VR experience from a psychophysiological perspective, point to a connection between sensorimotor engagement and learning but do not address *why* or *how*.

Further explorations require an in-depth examination of the learning involved. The current study extends our prior work by examining *how* students engage with the VR simulation in model-based reasoning. We seek to identify the patterns students use to interrogate the simulation model and how their strategies connect to perceptual affordances in virtual reality.

Method

This project is based on a design-based research methodology (The Design-Based Research Collective, 2003), following a co-design process (Penuel, 2019). Researchers collaborated with a science instructor to develop the VR simulation in Unity 3D to address a topic her students had difficulty understanding. The topic was introduced to course students in two 80-minute lectures using an active learning approach. The VR simulation was tested with a subset of her students in the Winter term of 2019.

The VR simulation environment & model-based reasoning activity

The subject of the simulation is a foundational but complex model of gene regulation in the bacteria known as the *lac operon*, or simply put, how a set of genes are turned on and off to regulate lactose metabolism in the E. Coli bacteria. Part of the difficulty in constructing a complete understanding of the lac operon is that it has two interconnected controlling mechanisms (negative feedback and rate of metabolism) that respond “intelligently” to fluctuating environmental conditions (Cooper, 2015).

Within the simulation, learners build the lac operon model and reason about its function under various conditions (e.g., high glucose levels). The model has 18 components, grouped into three types according to their role in the simulation: structural components, mechanistic components, and system-automated components (Table 1). The learning activity was facilitated by the lead researcher and consisted of the following phases:

Phase 1 – Learners completed the model by placing or throwing elements (structural elements) in their designated location along a placeholder DNA strand (similar to a “drag-and-drop” interaction but in 3D space; Figure 1).

Phase 2 – Learners explored how the model’s components behave by interacting with mechanistic elements to create new molecular and protein elements, effectively “running” the simulation (e.g., transcription with RNA polymerase, translation with ribosome).

Phase 3 – Once system-automated elements appeared, learners were prompted to reason about how the model functions (e.g., “What is happening here?”, “Why do you think…”). Since it was important for learners to notice certain interactive features and inter-level attributes of emergent processes in dynamic simulations, prompts were used as a scaffolding device to supplement the simulation (Chi et al., 2012). Feedback and prompts were consistent with facilitator-participant interactions in related studies (Roussou & Slater, 2020; Wilkerson-Jerde et al., 2015).

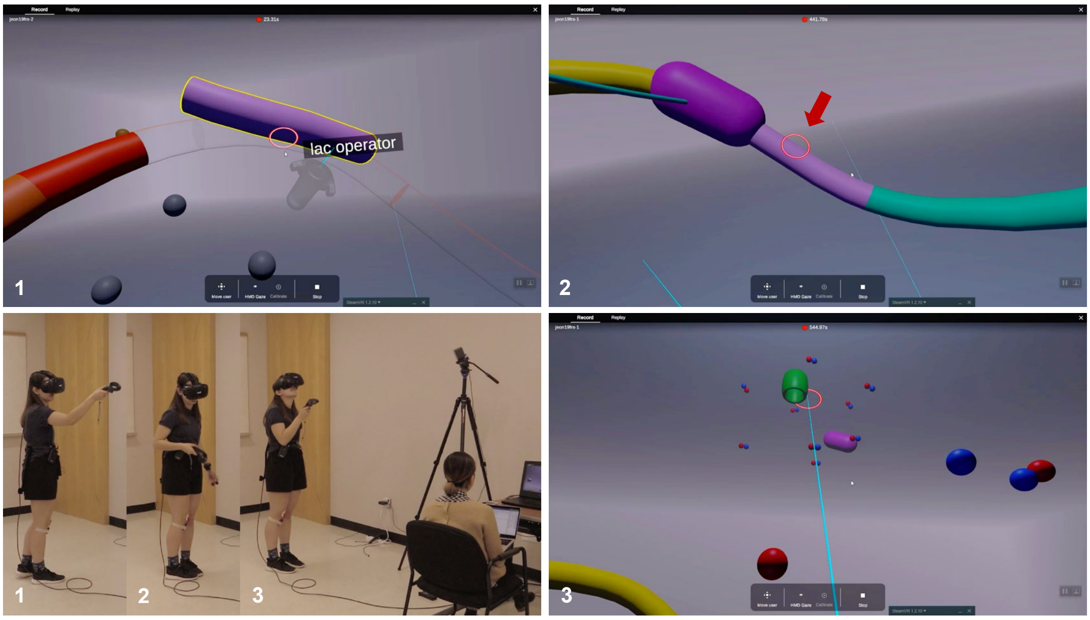

Figure 1. Images from the VR simulation, phases 1–3. Clockwise from top left: 1) Moving operator gene to DNA, 2) RNA polymerase transcribing the DNA to mRNA, 3) Permease protein transporting lactose into the cell. Bottom left: Participant positions in corresponding phases. Red circles indicate participant gaze fixations.

Table 1: Component types in the VR simulation and their relationship to the scientific model

Type of VR object	Description	Model component
Structural	Learner-controlled objects that form model structure	Individual genes (e.g., operator)
Mechanistic	Learner-controlled objects requiring interaction to modify simulated states of the model	RNA polymerase, ribosome, mRNA
System-automated*	Objects generated automatically by the simulation as a result of user interaction with mechanistic elements	Molecules (e.g., lactose, cAMP), proteins (e.g., beta-galactosidase, acetyltransferase)

**Two mechanisms involve system-automated elements that impact the model's function. One relates to a negative (–) feedback loop (stops function), and another relates to a positive (+) feedback loop (accelerates effects).*

Participants
Thirty-four students from an undergraduate microbiology course participated in the experiment (5 males, 29 females). Participants were recruited through class announcements and randomly assigned to either a seated or standing condition. The average age was 21.2 years; 15 did not have prior experience with immersive technology.

Procedure
Prior to the experience, participants completed a pre-activity questionnaire consisting of nine multiple-choice questions based on a concept inventory about the *lac* operon (Stefanski et al., 2016). As well, the questionnaire included questions about learners' prior experience with immersive environments and spatial ability. An HTC Vive head-mounted display retrofitted with integrated eye tracking (Tobii Pro VR, Tobii Group) was used. The VR experience itself was approximately 30 minutes long. Participants in the seated condition sat in a swivel chair, while participants in the standing condition freely moved within a 2.5 m^2 space. All participants held a controller in their dominant hand only. Audio, video, and screen recordings were captured, in addition to physiological sensing data. The lead researcher took field notes during the data collection period. Afterward, participants completed a post-questionnaire, which included a posttest (identical to the pretest) and questions about their experience. The entire session lasted approximately one hour, and participants were given a gift card as a token of appreciation.

Data sources and analysis

The primary data source for this study were video recordings of the VR sessions, which were transcribed by a text-to-speech service (https://otter.ai/) and corrected by two researchers. Other data sources collected provided contextual information about the learner and perceptions of their learning experience. To analyze the data, we first coded the content of facilitator-participant interactions (Chi, 1997) using the structure-behavior-function framework (Hmelo-Silver & Pfeffer, 2004). For example, exchanges coded as structure may begin with "What do you think *that* is?" (referring to the objects participants were looking at). Exchanges coded as behavior may begin with "What do you think beta-galactosidase does?" Those stemming from prediction questions such as "What do you think will happen?" and "Why did the repressor release from the *lac* operon?" were coded as function. Two researchers coded the exchanges, with the codebook established collaboratively from coding one transcript together. After coding slightly over 20% of the transcripts separately and achieving over 85% agreement (with all differences reconciled), the remainder of the transcripts were divided between the two researchers. The exchanges underwent further coding with an inductive approach following the constant comparative method (Gibson & Brown, 2009). Open coding on the exchanges was performed to examine how learners interrogated the model in VR. The researchers shared and discussed the codes and explored proto-themes. Finally, these codes coalesced as a set of four themes that described learners' patterns of use (Thompson & Reimann, 2010). Particular attention was paid to the affordances of the VR environment for supporting learners to reason around models.

Results and discussion

SBF model engagement with VR simulations

This study seeks to uncover patterns of use when students are engaged in a model-based reasoning activity with VR simulations. However firstly, we needed to establish *which* aspects of the model students engaged with. The content analysis of facilitator-participant interactions found that students engaged with the function of the lac operon model most, taking up 50% of exchanges that belonged to the SBF framework. This was followed by the model's structural features, which comprised 26% of facilitator-participant interactions, and then behavior of individual components at 24%. In some ways, the analysis of facilitator-participant interactions from an SBF perspective speaks to how well a VR simulation can support students' conceptual engagement about the lac operon model. We demonstrate that the activity maintained a strong focus on the model's function, which was crucial for students to develop a deep conceptual understanding of the phenomenon (Hmelo-Silver et al., 2007). Because VR simulations offer highly tangible representation embedded in the learner's perceptual view, one might suggest that learners in VR simulations are at risk of focusing on structural features too much simply because they are easier to attend to visually. This study offers preliminary evidence that it does not have to be the case and that novices, such as the students in the foundational biology course, can be prompted through the design of the learning activities to engage with the VR simulation for examining the behaviors and functions of a system.

Other researchers have also explored ways in which an SBF framing of embodied activity can lead to shifts in explanations about superficial structures to the system's behaviors and functions (Danish, 2014). However, they caution that design decisions can influence whether learners' attention is directed toward or away from a complex system's key behaviors. More work is needed to understand how specific design features may cue learners' attention to complex phenomena in VR simulations.

Patterns of use in model-based reasoning with VR simulations

In this section, we present *how* learners engaged with the VR simulation. Below, we describe four themes regarding the patterns of use in a VR-mediated experience during a model-based reasoning activity. We also discuss the affordances of VR simulations for supporting each pattern.

Theme 1: Spontaneous, direct observations of model structural features

While interacting with the simulation, students noticed certain visual aspects of the model and wondered about them. Although many such comments were of surface-level features of the model, this seemed to motivate students' questions about their behavior. In S32 @ 13:24 she noted: "What is that blue thing on top of this? Is it Allolactose? … It just stays there?" and S12 @ 23:23 "Oh, what's this? Galactose acetyltransferase [aiming and pointing to the object to reveal its text label, reading aloud] … Where did that come from? … oh, there's another one." Instead of continuing to the next task as planned, the facilitator guided S12 to transcribe the lac operon again. She carefully observed the proteins that were produced as a result, which included acetyltransferase.

For students learning about complex phenomena with computational models, direct observation offers one method for grounding abstract scientific knowledge in the model (Markauskaite et al., 2020). Similarly, the learners in this study were attending to structural elements they see, drawing from lower-level perceptual inputs, but the nature of their verbal observations was unprompted. An important distinction of the student observations in this theme from other inquiries about the model's structural components is that the exchanges were driven by the learner's own curiosity. Importantly, they (sometimes) led to deeper level investigations about the components, such as neighboring structures, interrelationships, and mechanisms involved. We posit that being perceptually situated in the molecular-scale of the model in 3D space facilitated students' spontaneous, direct observations, which in turn encouraged self-directed questions and deeper reasoning beyond surface-level features of the model. The unprompted observations and curiosity about model elements also relate to a correlation between positive emotions (e.g., motivation, enjoyment) and learning in VR (Makransky & Lilleholt, 2018).

Theme 2: Immediate situated feedback of model processes

Throughout the VR session, students were asked about the behavior of objects they interacted with. Students answered verbally and were then prompted to replicate their answers' through interaction with the simulation. In this way, student feedback was situated in experiencing the model's processes, such as in S10 @ 17:42. When asked, "What does [the repressor] do?" she answered, "It can bind to the operator to stop transcription?" When prompted to demonstrate this, the episode continued:

> S10: OOoo allolactose bound…the repressor…now is binding
> R: It wasn't binding before. Why is that?
> S10: Because the allolactose bound to it, so we have conformational change…cool.

S10 answered correctly but did not appear confident. Having "seen" the process validated her thinking and completed her understanding of the repressor's role in regulating the lac operon (i.e., negative feedback loop).

When students did not know how to respond to questions about the model, they were guided in the simulation to discover the answer. For example, when S28 @ 28:40 was asked, "What does allolactose do?" she responded with, "It allows lactose…is it? I can't remember…" S28 was guided to create a copy of the repressor. At that point, she observed allolactose binding to the repressor @ 30:15 "So the mRNA was put into the ribosome, created lac I repressor…and then attached to it is the allolactose." She successfully identified the structure in a new context. Upon observing the weak transient intermolecular attraction between the lac operon and the repressor, S28 initially (erroneously) conjectured that the repressor could indeed bind to the operator. However, as soon as the allolactose molecule bound to the repressor, S28 saw that the repressor detached from the DNA @ 30:48. She observed, "So when the repressor is attached, allolactose is not." Throughout the above episode, S28 explored the model intending to understand the role of allolactose. With each interaction, she attended to the subsequent dynamic behaviors of related structural components and directly observed the emergent nature of intermolecular attraction.

Episodes related to this theme were typically related to students' answer-seeking efforts or to demonstrate their understanding of model component behaviors. It is thought that our vestibular and proprioceptive senses (unconscious sense of body position, movement, and acceleration) are involved in the encoding, storing, recognizing, embodying, and recalling of spatial information about our environment and of our orientation within immersive VR (Krokos et al., 2019). The immediacy of "experiencing" dynamic feedback as students interacted with structure components likely supported the construction of embodied mental models that are situated in the first-person perspective (Glenberg, 1999). In cases where the learner's verbal response 'matched' what they saw, the experience validated their own mental model. Verbalizations may be encoded along with memory traces of their virtual reality experience. Conversely, in cases where the outcome is unexpected, learners were afforded an opportunity to confront their erroneous and fragmented understanding, allowing them to recognize the need to construct a more complete mental model.

Theme 3: Immersion of multiple simulated states in sequence

Students examined the simulated model under several distinct conditions. They began with the most basic variation with no external lactose or glucose molecules and culminated in a simulation version with high levels of lactose and glucose. Between "variations" of the model, students were asked to describe differences between the current version and the previously examined simulation. For example, after exploring a model with glucose present but not lactose (2^{nd} variation), S9 was presented with a version of the simulation with lactose only (3^{rd} variation). When asked to examine the differences between the two environments @ 21:29, S9 immediately noticed, "The cAMP is back…Okay, so before there's no CAP proteins associated, there's no cAMP bound to the CAP protein." Upon further prompting @ 21:48, he continues to recall details about the positive feedback mechanism:

R: And what else is different about the CAP protein?
S9: There's two of them bound together.
R: Yeah…what do you think will happen when the DNA is built?
S9: CAP protein should bind to the C site.

Later once the DNA was completed, when asked, "Did something happen on the DNA strand?" S9 comments @ 23:51, "Same thing as before the cAMP protein bind to the C site." In which he referred to the first variation of the simulation. He recalled elements of the positive feedback regulatory mechanism. He later made causal connections between the presence of glucose, the absence of cAMP, lack of CAP protein dimerization, and binding to the DNA — this ultimately suppressed the model's efficiency to metabolized lactose.
Presenting variations of the model in a sequential manner fostered the cyclical nature of the discovery process and supported a natural affordance of virtual reality to immerse students in a single alternate reality one at a time. Akin to using a compare and contrast strategy to examine epistemic frames (Collins & Ferguson, 1993), students recognized how the model might function under different circumstances and began to appreciate the model's emergent properties. Exploring increasingly complex variations allowed students to gradually develop progressively more sophisticated mental models and reason about the model as a dynamic system.

A drawback to this approach became apparent when a few students had difficulty recalling variations of the simulation. For instance, S7 acknowledged that something looked different but could not pinpoint exact details @ 14:48 "Oh, there's no um…the proteins look different here, but there's no inhibitor, the red thing is gone." Furthermore, S7 did not recognize that the red repressor was produced from interacting with the simulation (rather than appear at the outset). When students experienced difficulty recalling recent events and showed physiological markers of stress (from sensor data), it suggested that they were experiencing cognitive overload. Making connections amongst different aspects of a complex system taxes one's working memory (Perkins & Grotzer, 2000). At the same time, there are additional perceptual and proprioceptive processing demands in VR, which further limits working memory capacity. The issue of cognitive overload presents a fundamental design consideration, particularly for learners sensitive to simulator sickness and who have less prior domain knowledge.

Theme 4: Inquiry across structure, behavior, and function of the simulated model

In many instances, when students were asked to predict how the model would function, student responses spanned scalar levels, characteristic of mechanistic reasoning (Krist et al., 2019). For example, the facilitator posed to S1 @ 29:21 "What happens when you try to transcribe the repressor?" S1 responds, "Right…it will produce the repressor now. I don't think it will bind. The lactose can be broken down by the (beta-)galactosidase, and we have allolactose present, and it will bind to the repressor…it will remove it from the operator." S1 accurately identifies each of the elements (lactose, beta-galactosidase, allolactose) in the causal chain and the necessary behavior for the event to occur (beta-galactosidase breaks down lactose into allolactose and galactose).

Several episodes began as examinations in one of the SBF components but later spanned across the other categories. For example, S12 @ 19:36 noticed that the repressor was disassociated from the DNA ("Oh, yeah, it's already off"). Upon prompting, "What made [the repressor] come off?" S12 attended to the interrelationships between the structures around the repressor and reasons about them to discover the answer:

> Now it's back on there. Oh, there's a… it's a… it's one of the sugars that is broken down like glucose, right? What are the blue ones? It's a blue one. I'm not sure which one that is. There. Oh, allolactose…And that one's lactose. So, it's taking the lactose from that comes through the membrane, and then the beta… the B-gal [beta-galactosidase] separates it into galactose and allolactose and then…oh where did it go? Oh there. Okay. And then it binds to the repressor. And then it's not…

The episodes above illustrate the VR simulation's affordance to act as an experimental 'sandbox' by offering several decision paths for the learner to engage with various aspects of the model from the same perceptual context. Beyond interacting with the model in designated environmental conditions, the variables can be manipulated from within any scenario (i.e., increasing/decreasing glucose and lactose levels). These and other features opened up possibilities for supporting student-interest-driven inquiries in an uninterrupted, natural interaction flow. Future designs can draw on work with multiple representations for supporting more abstract reasoning. One argument that concrete materials can support abstract reasoning is connected to how well external representational forms can be designed—to explicitly promote inferences from perceptually salient features to correspond to abstract concepts (Goldstone & Son, 2005). Investigating design features in VR simulations for bridging concrete and abstract understandings of complex phenomena is an exciting direction for future research and serves as a promising area for understanding embodied cognition in learning contexts.

Conclusions

This paper offers preliminary support for the use of VR simulations to facilitate model-based learning activities for novices to understand complex phenomena. Although certain simulation affordances discussed are tied to the learning activity design, we suggest that the activity and form factor together confer advantages for novices to understand complex phenomena by grounding conceptually abstract entities (like negative feedback loops) into concrete 3D representations for observation over time. Learners not only focused on functional features of the model more frequently than structural or behavioral mechanisms, but they also exhibited patterns of use that were conducive to interrogating deeper interrelations of a complex genetic regulation system.

Abstract: This online experiment, involving 28 high school students, investigates frequencies and types of misconceptions while learning natural selection via two types of simulation modules. The experimental group uses an agent-based model which characterizes *P*attern, *A*gents, *I*nteractions, *R*elations, and *C*ausality (PAIR-C) features while the control group employs a commonly used PhET simulation. Although the pre-posttest does not capture significant differences between the two conditions, a set of non-leading prompt questions embedded in both simulation modules successfully captured the differences. Students from the experimental condition revealed fewer frequencies and categories of misconceptions and scored significantly higher in explaining one type of common misconceptions as well as responding to objective prompts than the control condition. Our finding indicates that the PAIR-C simulation module might have a better effect in reducing misconceptions. This study manifests strong potential in using a well-structured online simulation module to diagnose and address students' misconceptions in learning natural selection.

Introduction

In our increasingly interconnected world, issues that emerge from local circumstances can give rise to complex global challenges (Wilensky & Jacobson, 2014). To prepare future generations to become contributing members of society as we move into the post-pandemic era, educators are at the forefront to create order out of the complexities. Helping students understand how a complex phenomenon is formed and why it is happening is critically important for formulating scientific predictions and reasonable decisions.

Many natural and social phenomena can be conceptualized as emergent complex systems. A complex system is a system composed of many elements that interact with each other and their environment. Researchers use the term "emergent process" to describe how macro-level observable patterns emerge from micro-level interactions between numerous independent entities and the resultant patterns are called "emergent phenomena" (Wilensky & Jacobson, 2014). Numerous researchers indicated challenges in introducing the concept of emergent complexity in traditional science curriculum (Yoon et al., 2018; Basu et al., 2015; Hmelo-Silver et al., 2015), and reported that high school students often have difficulty in learning the interactive components of complex systems, holding persistent misconceptions in interpreting emergent processes from a sequential mindset in science classrooms (Chi, 2013; Dickes et al., 2016).

Therefore, the advancement of teaching emergent complexity requires more innovative instructional methods rather than the current traditional approaches. Our objective in this study was two-fold. The first objective is to draw upon the PAIR-C framework (Chi, under review) and agent-based modeling (ABM) literature to develop a simulation module that will constructively engage youth in observing and explaining complex systems. The second objective is to examine the effectiveness of using this simulation module to diagnose and address students' misconceptions in learning the emergent process of natural selection. To this end, the simulation module designed in this study will be used to provide an alternative instructional approach and help transform complex system teaching into flexible and efficient online modules.

Theoretical perspectives

The PAIR-C framework

Despite earlier research that proposed frameworks to characterize complex systems (Jacobson et al., 2011; Hmelo-Silver & Pfeffer, 2004), we employed the PAIR-C framework to create our simulation module because of three unique reasons. First, PAIR-C provides an ontological framework representing two kinds of processes: sequential processes feature linear individualistic causality; emergent processes feature nonlinear collective causality. Second, PAIR-C acknowledges that Patterns, Agents, and Interactions are three dimensions shared by both processes. Third, the Relations and Causality dimensions discriminate between the two kinds of processes from seven aspects. These aspects later become guiding principles for the simulation module design (see Table 1).

Within the PAIR-C framework, *P*attern describes the overall changes by a process that is often visible and meaningful, *A*gents (internal) are elements that participate in the process which produces the pattern (external agents interact with internal agents but do not participate in the pattern), the *I*nteractions of the agents refer to how the agents of the process interact, the *R*elations among the interactions compare agents' interactions, and the *C*ausal relations between the agents-pattern refer to how the interactions between agents produce patterns in emergent processes. The causal relations are also referred to as causal mechanisms with two implications.

Table 1: Seven aspects from the PAIR-C framework to discriminate between two kinds of processes

	Aspects	**Sequential Processes**	**Emergent Processes**
***R*elations among the interactions**	1. The set of interactions available to all agents 2. With whom agents can interact and when for individual interactions 3. Occur in serial order? 4. Conditional dependency: Occurrence of interactions dependent on prior outcomes?	1. Distinct set 2. Restricted other 3. Serial ordering 4. Dependent	1. Same set 2. (Not restricted) Random 3. Simultaneous 4. Independent
***C*ausal relations between the Agents-pattern**	**Causal Mechanism** 5. How the pattern transforms: Qualitative description 6. Agent-pattern causal mechanism for the perceptual pattern: Quantitative computation	Cumulative causal mechanism 5. Additive pattern 6. Cumulative summing of subsequent interactions between units of time	Collective causal mechanism 5. Converging pattern 6. Collective summing of all the agents' interactions within each unit of time
		Two implications	
	7. a. Identifiable causal agents responsible for the pattern b. Alignment between the agents and the pattern	7. a. Single-agent or a group - Centralized control - Special status - Intentional b. Align: congruous	7. a. All agents or a collection - Decentralized control - Equivalent status - Unintentional b. Not align: Incongruous

Common misconceptions in learning natural selection

Researchers (Chi et al., 2012; Gregory, 2009) have recognized that students demonstrated common misconceptions such as teleological perspectives and centralized deterministic mindsets in their reasoning and explanations about natural selection. To address this problem, we aimed to design an agent-based simulation module to help students better observe the mechanisms that drive the emergence of population-level phenomena from smaller scales of agent interactions, understand the random and nonlinear characteristics of the systems, and adopt an unintentional and decentralized perspective in understanding the emergent process of natural selection.

Agent-based models and revisions

In agent-based modeling (ABM), the term "agent" indicates individual computational actors that obey simple rules. It is the *I*nteractions between these *A*gents that give rise to emergent *P*atterns in complex systems. Because the nature of ABM aligns well with the PAIR-C framework, we used the NetLogo agent-based modeling environment (Wilensky, 1999) to construct our simulation models. A recent meta-analysis on simulations for STEM learning found that when the simulation was very structured (i.e. students use the simulation with a prescribed path), it resulted in more cognitive gains than when the simulation allowed for more flexibility in the student interaction with the simulation (D'Angelo et al., 2014). Therefore, we decided to use ABM as a representational tool and design a structured learning trajectory for students to navigate the simulation module.

In searching for ABM simulations, we selected the NetLogo wolf-sheep predation model (Wilensky, 1997) and identified six issues within this model based on the PAIR-C framework. These were: a) The Patterns of current simulations focus on moving entities rather than representing dynamic changes across multiple generations; b) The way to introduce external Agents (e.g. wolves - predators) may induce misconceptions that external agents also participate in the pattern; c) Agents' Interactions (e.g. mating interaction; chasing interaction) are not visible in the simulation. Only the agents' actions (e.g. sheep randomly move) are shown; d) Relations among the Interactions are not visible from watching the random movement of agents; e) The Causal relation characteristics between the agents-pattern (how the pattern converges) are not displayed; f) The collective summing Causal mechanisms (how the pattern is produced) are not explained. We incorporated these identified issues and modified the wolf-sheep predation model in the PAIR-C simulation module. The resulting PAIR-C simulation module will be introduced in the Findings section.

Method

Participants and research design

This online experiment was conducted among 28 participants. These participants were high school students from two science extracurricular programs. Participants were assigned to one of two conditions. Students in the experimental condition (n = 14) were given three modules: 1) an overarching PAIR-C Process Module containing information about the concept of emergent causality by comparing and contrasting every day "emergent" and "sequential" processes; 2) a PAIR-C Natural Selection Lecture; 3) a PAIR-C Simulation Module. Students in the control condition (n = 14) were given three modules as well: 1) a Nature of Science Module, a traditional module introducing the philosophy and methods of scientific exploration; 2) a "Business as Usual (BAU)" Natural Selection Lecture; 3) a BAU Bunny Simulation Module. The BAU bunny simulation is created based on an interactive PhET simulation on Natural Selection. The study involves three tests: pre-test, post-test 1 (after the Natural Selection Module), and post-test 2 (after the Simulation Module).

Data sources

Several different data sources allow researchers to investigate the effectiveness of the PAIR-C simulation module over the BAU simulation module in terms of diagnosing and reducing misconceptions when learning the emergent process of natural selection. A repeated test measure (from pretest to posttest 2, from posttest 1 to posttest 2) was used to examine knowledge gains. Prompt questions embedded in the simulation module also revealed students' formative performance and misconceptions. A feedback survey inserted at the end of the module provided evidence on engagement, module clarity, and learning experience.

Each simulation module consisted of seven parts and three scenarios. Both simulation modules used two types of prompts. The first type of prompts consists of questions that expect students to find clues from observing the simulations. These questions include true or false (T/F) questions, yes or no (Y/N) questions, open-ended (OE) questions, and two-tiered questions (the first-tier is a Y/N question while the second-tier is an OE question asking for explanation). All of these questions were coded and scored based on PAIR-C features shown in Table 1. Overall, students in both groups answered a total of 9 open-ended questions and 21 objective questions which were matched as much as possible to be the same for both conditions. In addition to assessing how students understood the emergent process of natural selection, the second type of prompts was designed not to measure understanding but to better engage students while working through the simulation module.

Procedure and data analyses

The PAIR-C simulation module was operated using Google Form, through which the researcher could conveniently collect students' responses. To examine students' misconceptions about natural selection, we coded student responses to prompt questions within the simulation module. We deliberately designed non-leading prompt questions for the PAIR-C simulation module and the BAU Bunny simulation module to ensure the students' responses to the 9 open-ended prompt questions and the 21 objective questions were comparable across the two conditions. We used a two-step process to score students' responses to the 9 OE questions and later conducted statistical analyses. First, each open-ended prompt was scored for correctness (a score of 2 was given to accurate and complete answers; 1 for accurate but not complete responses; 0 for inaccurate responses). Second, for responses that scored 1 or 0, the responses were coded using the PAIR-C Framework for misconceptions in student responses. In this second step, we also marked undecided responses and other types of errors that led to that score (usually incomplete responses). The responses with scores of 2 were also screened to make sure they were not showing misconceptions. The coding rubric for each OE prompt question was established and checked by two experienced coders (See Table 2 for a sample rubric established by two coders).

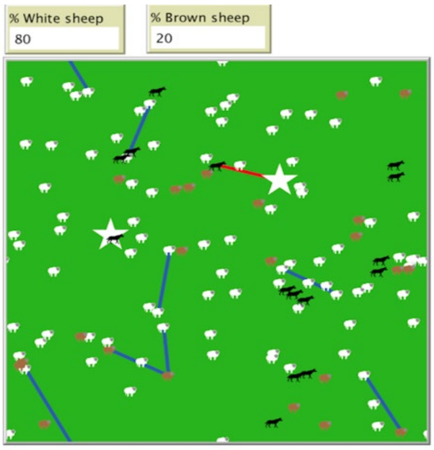
Table 2: The coding rubric and sample responses for prompt Q7b

Score	PAIR-C Simulation Prompt Q7b	Bunny Simulation Prompt Q7b
	Rubric: This question was designed to assess the understanding of the **collective summing** feature. • 2 (correct and complete): collective summing within each unit of time (primary feature) + mentioning one of the secondary features (e.g. misalignment; unrestricted relations) • 1 (correct but not complete): Only mentioning secondary features or implications • 0 (incorrect): showing misconceptions	
2	The number of white sheep is not always increasing, so this is not just about white sheep increasing via mating. Instead, this is a result of white sheep increasing or decreasing via mating, (**collective summing**) and brown sheep increasing or decreasing via mating. So this does not always result in the number of white sheep increasing (not just mating between white sheep; both brown and white sheep can mate **randomly**). OR Considering both the white sheep and the brown sheep, and the mating interactions of all sheep, the white sheep don't have to increase in every generation (**collective summing**), but the percentage of white sheep has an increasing pattern (not **align**).	The number of long-toothed bunnies is not always increasing, so this is not just about long-tooths increasing via mating. Instead, this is a result of long-tooths increasing or decreasing via mating, and short-tooths increasing or decreasing via mating. So this does not always result in the number of long-tooths increasing (not just mating between long-tooths; both long and short-toothed bunnies can mate). OR Considering both the long-tooths and the short-tooths, and the mating interactions of all bunnies, long-toothed bunnies don't have to increase in every generation, but the percentage of long-toothed bunnies has an increasing pattern.
1	only explains misalignment but not collective summing. The percentage of white sheep over brown sheep is always increasing but the number of individuals may not always increase. **(Only mentioning not align implication)**	doesn't say long-toothed bunnies always increase or not; just mentioning long-tooth has an advantage due to environmental factor
0	White sheep are always added to the population between generations to create a pattern of white sheep becoming more common. As white sheep increase, brown sheep will decrease. **(Misconception: align, cumulative summing)**	When time goes on, the long teethed bunny population increases. Therefore, in each generation, long-toothed bunnies are added to the population.

Findings and discussion

Designing PAIR-C simulation

The original wolf-sheep predation model described a set of rules that govern the behaviors (e.g. to move, to reproduce, to eat-sheep, to grow-grass, etc.) of individual computational agents (e.g. sheep, wolves, and grass). As the model runs, all agents concurrently act out their rules without explicitly showing the interactions. To let the audience see what is exactly happening, we made the interactions between agents visible by adding rules to represent interacting agents (e.g. sheep-sheep reproduction, wolves-sheep chasing, See Figure 1 for example).



```
;;; Sheep rules ;;;
to reproduce
  ask sheep [
    let mate other sheep-here
     if count mate >= 1   [
           create-link-with (one-of mate)
      [set link-age 1
      set thickness 0.3
      set color blue]

;;; Wolf rules ;;;
to eat-sheep
let prey one-of sheep-here
  ;; chase a random sheep ;;
  if prey != nobody  [
      create-link-with (prey)
      [set link-age 1
        set thickness 0.3
        set color red]
      if [color] of prey = white
  ;; successfully caught a white sheep ;;
      [ if random-float 100 < 80
        [ask prey [ set size 3
                    set shape "star"
                    set color white]
;;the chased white sheep become bigger for students to see clearly;;
;; the white sheep disappeard to a white star to indicate deadness ;;
```

(a) (b)

Figure 1. The revised wolf-sheep predation scenario (a) with codes (b).

Upon finishing the revision of models, we had addressed the problems of visualizing interactions (problem c) and introducing external agents separately in a later scenario (problem b). To solve the remaining problems, we proceeded with creating the online simulation module. The PAIR-C simulation module contains four basic elements to fix the remaining problems: simulation videos, ABM screenshots, animated pictures, and nonleading prompts. There are 6 simulation videos in the module. Some videos were edited with subtitles that convey clarifying information about the generation periods, the number of sheep, or the percentage of sheep. We also captured static screenshots to show relations among sheep interactions (problem d) as well as generate dynamic patterns across different time periods (problem a) to demonstrate convergence and collective summing mechanism (problem e and f). Meanwhile, animated pictures were used at two different locations to direct students' attention to specific simulation features so that they could intuitively draw implications (i.e. decentralized, equivalent status, unintentional property) to interpret the causal relations between the agents and pattern.

Contrasting PAIR-C simulation with non-PAIR-C simulation

It was found that the PAIR-C simulation is different from the non-PAIR-C (BAU bunny) simulation in three major aspects, considering how students interact with the simulation (interactivity); what is being represented (visibility), and what is being taught in the simulation (learnability).

Interactivity

The PAIR-C simulation was used as a multimedia presentation tool which includes simulation videos, ABS screenshots, and animated pictures. Students interact with it mainly by observation while they could also adjust the speed, replay the simulation videos as well as responding to the embedded prompts at their own pace. The prompts require students to generate new inferences beyond observing or manipulating the simulation videos. Noticeably, the non-PAIR-C simulation is often an embodied simulation tool that allows students to manipulate conditional variables within the simulation. The non-PAIR-C simulation often features an active mode of cognitive engagement when students are only manipulating the simulation (Chi et al., 2018) without generating new inferences from the presented simulation. Besides, in the context of learning natural selection, allowing the unrealistic agency to manipulate simulation tends to reinforce misconceptions about intentionality and special status (see Table 1). In this study, the non-PAIR-C bunny simulation was presented through videos in the same structure as the PAIR-C condition.

Visibility

Students often have difficulties seeing the mechanisms that produce the dynamic changing pattern in simulations (Chi, 2005). The PAIR-C simulation solved this problem by using "links" to visualize interactions among agents and showing collective interactions across multiple generations in multiple ABM screenshots. In contrast, the non-PAIR-C simulation only shows agents' actions or movements at each generation. The bunny simulation directs attention to moving entities rather than how the pattern is produced. For example, in the bunny simulation, students are not able to tell the random nature of the interactions among bunnies through the Pedigree chart (see Figure 2).

(a) (b)

Figure 2. Comparing simulation interface (a) PAIR-C simulation and (b) Bunny simulation.

Learnability
In the PAIR-C simulation module, collective interactions of all agents are counted, nonlinear agents-pattern causal relations that incur misconceptions are explicitly emphasized, and aspects of the Relations among the Interactions are also examined (see Table 1). Conversely, the non-PAIR-C simulation showed individualistic actions of a subgroup, represented linear causal relations between conditions and their consequences on the pattern. Features of the Relations are always not mentioned.

The PAIR-C simulation module

Pre-posttest
A repeated test measure was used in this study, including the pretest, posttest1 (given after the Natural Selection Module), and posttest2 (given after the Simulation Module). This test consists of 20 multiple-choice questions. Among them, 12 questions were hard-level questions, which assessed understandings of different PAIR-C features in the context of natural selection. There were also 5 medium and 3 easy-level factual questions. The majority of these questions were adapted from multiple conceptual inventories (e.g. CINS, CANS, AAAS, and past AP Biology Exams from College Board) with two hard-level questions created by a senior researcher. To determine whether students' scores improve for hard-level questions over time, we conducted a paired samples T-test. The analysis showed that there was no statistically significant improvement from pretest to posttest2 for the control condition, while there was a statistically significant improvement from pretest to posttest2 for the experimental condition, ($t(13) = -2.86, p < 0.05$). Using pre-test hard questions as a covariate, we conducted ANCOVA and compared students' scores on post-test2 hard questions to see if we could find a significant difference between the two groups. There was no statistical significance found between two groups, $F(1, 25) = .388$, $p = .539$, partial $\eta 2 = .015$.

Within module assessment
To examine differences in scores for PAIR-C features between conditions, we combined open-ended questions that shared the same features and ran independent t-tests for each feature. Most of the tests were not significant, except for one type: collective summing (see Figure 3). This shows that the PAIR-C simulation group had significantly higher scores than the BAU bunny simulation group when explaining the collective summing mechanism ($t(26) = 2.82$, $p < 0.01$).

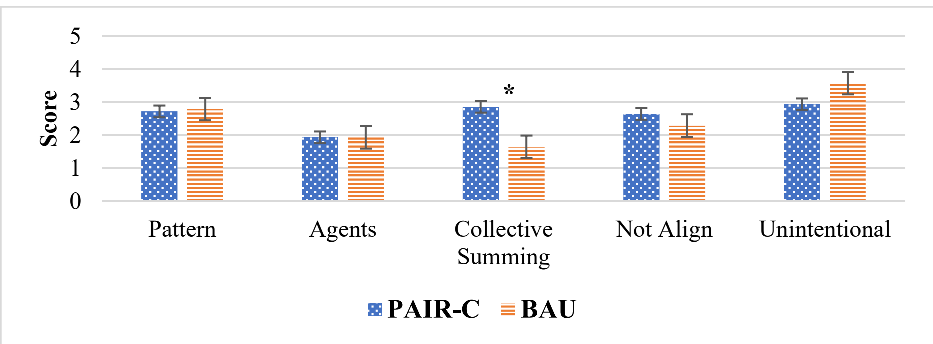


Figure 3. Average scores by condition for open-ended prompt questions.

The number and type of misconceptions that were found in student responses to the open-ended prompt questions were also counted. Overall, there were 21 misconceptions found for the BAU condition while there were 15 misconceptions found for the intervention PAIR-C condition, including the undecided misconceptions. We found that there were 7 instances of restricted relations misconceptions for BAU while there were none for PAIR-C. Because numerous responses demonstrated at least two categories of misconceptions based on the PAIR-C framework, we decided to present the frequency of misconceptions instead of the number of student responses showing misconceptions (See Figure 4).

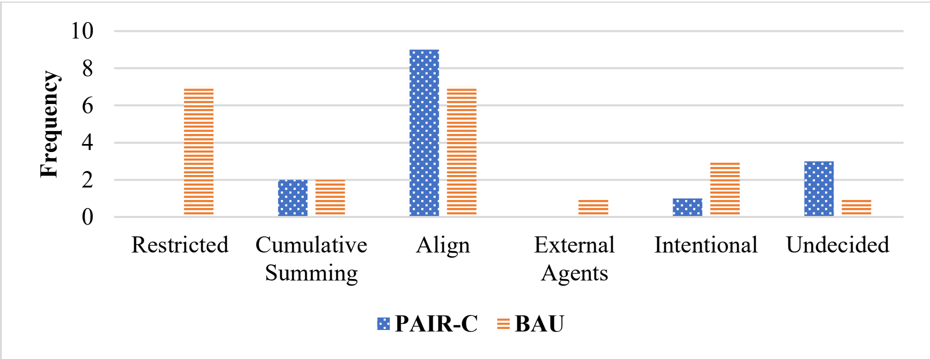

Figure 4. Frequency of misconception types by condition for open-ended prompt questions.

In addition to the open-ended prompt questions, there were 21 objective prompt questions in each of the simulation modules. The 21-question is composed of 2 items on environmental conditions;12 items on Relations (unrestricted, same set, simultaneous, independent); 1 on the external agent; 2 on no causal agent; 1 on non-alignment; 2 on converging pattern; 1 on collective summing. The average scores of these 21 objective prompts were 19.64 for the PAIR-C condition, and 16.50 for the BAU condition (See Figure 5 for the score distribution). A two-sample t-test was conducted which showed a statistically significant difference between the PAIR-C condition and the BAU condition ($t(18) = 3.83$, $p < 0.01$). This result indicates that our PAIR-C simulation module might have a better effect in reducing common misconceptions.

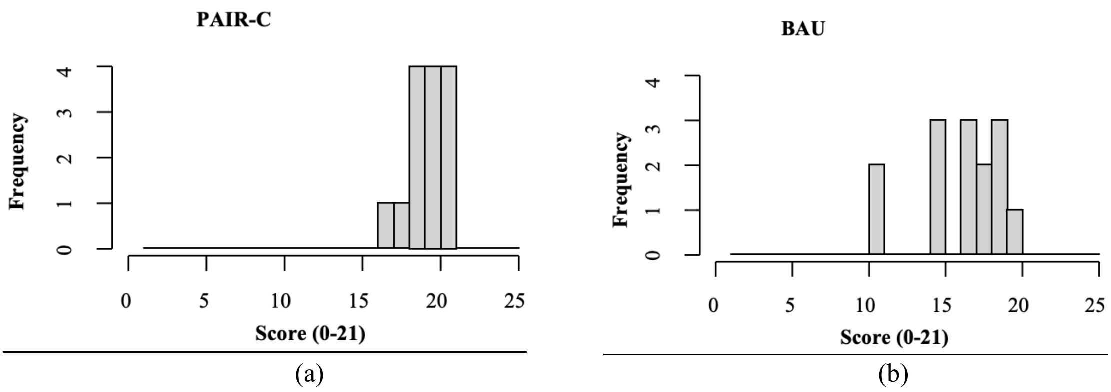

Figure 5. Frequency of score distribution for (a) PAIR-C and (b) BAU conditions on 21 objective prompts.

Feedback survey

The post-simulation survey questions asked students to report engagement, module clarity using a 1-5 Likert Scale. Students in the experimental condition reported an average of 4.14 for engagement and 4.21 for clarity. For the control condition, the average scores for engagement and clarity were 3.86 and 3.36 respectively. We also asked students to describe their experience in using the simulation videos. Nine students from the PAIR-C condition reported that they only played the simulation once. However, only two students from the BAU condition expressed that they played the simulation videos once. Other students from the BAU group stated that they replayed the majority of the videos multiple times. This further manifests the efficiency and clarity of using PAIR-C simulation to represent agent relations among interactions as well as explain the causal mechanism for the emerging pattern. Several students from both conditions suggested that the simulation module could be improved by including more simulation models as examples, and would be more engaging if a narration was provided.

Conclusion

We believe that our PAIR-C simulation module has scholarly implications for simulation-based online teaching practice. Our results highlight the importance of using a simulation module grounded in the agent-based modeling approach and the PAIR-C theoretical framework to scaffold student learning in natural selection as emergent processes. From sorely looking at the simulation prompt data, we found that the PAIR-C simulation with non-leading prompts was able to reveal some important misconception features that other traditional simulations could not capture. However, this study could not validate the effectiveness of the PAIR-C simulation without comparing it with standard agent-based simulation. To address this limitation, future works can focus on conducting a stand-alone study to compare the improved agent-based simulation with PAIR-C features and standard agent-based simulation without PAIR-C features.

Interlocking Models as Sites of Modeling Practice and Conceptual Innovation

Chris Georgen, Eve Manz
cgeorgen@bu.edu, eimanz@bu.edu
Boston University

Abstract: A central goal of both professional and classroom-based scientific communities is building and testing explanatory models of the natural world. The process of modeling a complex phenomenon often requires working across representational systems of differing scales, modalities, and purposes. When put into contact, entities across multiple representational systems can become related or "interlock." This paper describes how students drew from multiple representational systems to construct "interlocking models" and how reasoning with interlocking models supported meaningful practice and conceptual innovation. We present the design and findings from the implementation of a fifth-grade investigation into the conservation of matter. We describe the process of how contradictions between representational systems surfaced and led to interlocking models. Our findings suggest that students can recognize and take up interlocking models that provide a purpose for students to critique and refine their understanding.

Introduction

While model-based reasoning and explanation is a driver of science practice and increasingly of science education, how to design and support learning environments where young students take up modeling as a meaningful practice—one that is purposeful, agentive, and conceptually productive—is an enduring question (Berland et al., 2016; Manz, 2012). In this paper, we explore what can be learned about classroom modeling from a key practice of laboratory science—interlocking models. We share findings related to the challenges and opportunities of designing for interlocking models in a fifth-grade investigation of the conservation of matter. We conclude with insights into how students productively recognized and took up the tensions and pushbacks surfaced by contradictions and interlocking models.

Opportunities and challenges in classroom modeling

Consistent with philosophers and sociologists of science, we conceptualize science as a modeling enterprise (Giere, 1990; Windschitl et al., 2008). Science involves constructing, evaluating, aligning, and refining models in light of their joint bearing on a question or purpose. Models take on many representational forms, including equations, theories, diagrams, and simulations. In classrooms, orienting activity around developing, testing, and revising models can support students to develop science understandings as they engage meaningfully in scientific practice (Gouvea & Passmore, 2017). Yet, how to design and implement learning environments where students make progress on important science ideas as they develop and revise models is not yet fully understood. Teachers can take up models as places to hold ideas or orient so fully to developing canonical models that students have little agency in constructing or critiquing models (Lehrer & Schauble, 2006). Students, who are new to the modeling game and conduct it in communities of practice that differ substantially from those of scientists, may not necessarily take up models as tools for reasoning and communicating (Schwarz et al., 2009). Researchers are still debating how exactly to prioritize students' authorship of science practice as compared to the development of canonical understandings that were developed over periods of time and with tools impossible to instantiate in the classroom (Osborne et al., 2018). To orient our work on these challenges, we draw from situative and socio-cultural accounts of learning that treat practices and ideas as resources participants draw on, re-organize, and over time stabilize as they engage in meaningful activity in communities (Hall & Greeno, 2008). From this perspective, the purposes that students take up for modeling (to demonstrate understanding, to compare ideas, to recognize and orient to contradictions across ideas and evidence) are both of central importance in supporting meaningful science practice and are themselves emergent from activity. Key questions, then, are how (1) those purposes can emerge in activity and (2) how modeling can be productive, from students' point for view, for their conceptual work. Next, we consider how the use of interlocking models can help the field make progress on these questions.

Interlocking models in science laboratories and classrooms

Rather than working with models in isolation, scientists align and integrate multiple models as they work toward building a more complete explanation of a phenomenon (Nersessian, 2010; Rouse, 2015). Nersessian describes how through this process models can "interlock" or come to be taken as bearing on one another. Once interlocked, one model becomes a potential site for new questions, challenges, or refinement of another. For example, neural engineering laboratories construct models consisting of the recreation of phenomenon *in vivo* (e.g., neural networks) as *in vitro* physical models (e.g., dish of neurons) and computational re-descriptions of models (e.g., simulation patterns for the dish). Accounts of interlocking models in science practice offer several potentially useful implications for supporting students to engage in agentive, purposeful, and conceptually productive modeling. First, individual moments of modeling are open-ended and tentative—with no promise that they constitute "progress." Second, interlocking models form a fabric that is not seamless, as information from different representational systems can be inconsistent or contradictory. Contradictions between representational systems can point toward conceptual gaps, discrepancies, and tensions. That is, a key source of conceptual innovation in science is the moments where models "speak" to each other and the differences in what they "say;" these differences can provoke problem-solving processes that drive the refinement of questions, methods, and tentative explanations.

In K-16 science education, designs for model-based learning such as the *bifocal modeling framework* (Blikstein, Fuhrmann, & Salehi, 2016) and *coupled methodological systems* (Gouvea & Wagh, 2018) have used multiple representational systems. These designs have primarily focused on how simulations and physical experimentation can support each other, showing that one representational system can become a source of questions for another and that differences in results can support students' further inquiry. In this paper, we sought to build from this work by pursuing a closer analysis of (1) when and how students come to see representational systems as bearing on each other and (2) how interlocking models can support moments of conceptual innovation, thus allowing us to better understand how educators might design for and support interlocking models in classrooms. To situate our analysis, we first describe the design of a fifth-grade science investigation into the law of conservation of matter in which students worked with multiple representational systems. We then describe how contradictions among emerged as a key mechanism that allowed students to begin to make connections across representational systems, treating them as models that could interlock, or bear on each other. We show how, through questioning and making sense of the contradictions, students developed interlocking models that served as tools for further reasoning.

Research context and design

The work reported here takes place within a larger design-based research study involving a multi-year co-design partnership (Penuel, Roschelle, and Schechtman, 2007) with a public school district in the northeast US. The goal of the project is to redesign the elementary school science investigation to better capitalize on forms of uncertainty that are usually removed from children's experience with empirical activity. In this paper, we report on the second implementation of an investigation co-designed with two teachers. The investigation addresses fifth-grade NGSS standards related to matter and its interactions, specifically that students "measure and graph quantities to provide evidence that regardless of the type of change that occurs when heating, cooling, or mixing substances, the total weight of matter is conserved" and "use a particle model to explain common phenomena involving gases and phase changes" (NGSS Lead States, 2013). Like other standards that we have unpacked with teacher co-design teams, these pose challenges for engaging children in meaningful and agentive modeling practice in which they make progress toward the canonical ideas held in the standards. First, why would students ask about and focus on the weight of substances as a measure of amount, rather than more perceptually available attributes, such as volume? Second, how could we support students to experience weight as not changing, when small fluctuations could be interpreted as confirming prior ideas? Third, how could we set this work in a context where students were making sense of a phenomenon they could experience and wonder about, when water—the only substance to exist in all three phases within earth's temperature ranges – behaves differently (expands as it freezes) and must be explained by a molecular, rather than particle, model? Fourth, how could students come to see the molecular models that they had been developing as useful for understanding changes (or lack thereof) in the size and weight across phase changes? Like many classroom investigations, the questions, measures, evidence, and conceptual entities that children are expected to use are only "obvious" in light of entire set of models that scientists have stabilized in relation to each other.

This context therefore provided a fruitful opportunity to explore using interlocking models. We developed a sequence of activities (Figure 1) in which students engaged with different representational systems: (1) watching a **video** of a glass bottle filled with water and placed outside in cold weather eventually exploding, (2) building **pencil and paper models** to explain why the bottle broke using molecules (drawing on previous work in which they had used a simulation and models to explore why dye diffuses at different rates in different water temperatures), (3) testing questions related to whether water was "getting bigger" using an **empirical investigation**, (4) creating a **data representation** to see what most of the vials did, and (5) returned to their **initial**

models and a **simulation** to develop a class model of water molecules spreading out when frozen—explaining the fact that the same amount, or weight of water, can take up more space when frozen and break a glass bottle. This process set up an introduction to the law of conservation of matter as a sensemaking resource with explanatory power, rather than as either an answer that students could arrive at through developing conceptual models or the "correct explanation" they could be told. Table 1 shows how we considered each of these to be distinct representational systems with specific resources and the potential to interlock.

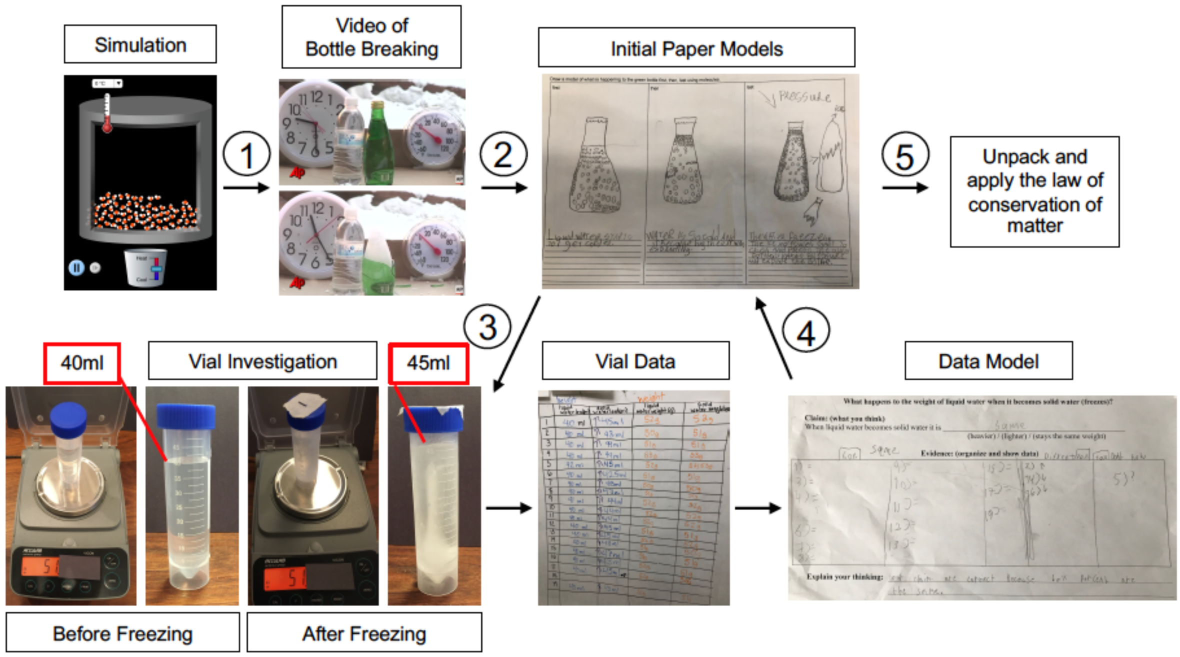

Figure 1. Sequence of Activities

Table 1: Overview of representational systems

Representational System	Conceptual and Representational Features	Opportunities for interlocking models
Simulation	Micro-level molecular representation of phase change in water; highlights how molecules move and arrange with temperature; keeps the number of molecules static; temperature an adjustable parameter.	Introduced in the context of water molecule behaviors under increasing temperatures; exploring the parameters and boundaries of the simulation led to questions about temperature decrease; offered students a canonical model of molecular behavior to apply to the bottle breaking; later, a return to the simulation used refute or support theories of water expansion.
Video of the bottle breaking	Macro-level perceptual representation of phase change; offered access to familiar sensemaking resources (e.g., pressure, air, materiality); static parameters but replayable.	Provided resources to support initial models of the bottle breaking and a context to reason with water getting "bigger" or taking up more space as it freezes.
Pencil and paper models	Student generated micro- and macro-level representation of how and why the bottle breaks using molecules; flexible and open-ended space for students to propose tentative explanations.	Context for students to bring together resources from the multiple representational systems to explain and refine explanations of the bottle breaking at different points in the inquiry.
Empirical model: Vials	Empirical; draws attention to measures of weight and volume (water level) and supports comparison across phase change	Observable and measurable evidence for water level; evidence that weight does not

filled with water and frozen		change, which can connect to number of molecules
Data model: Organized data set	Students organize and compare data to make visible what "most of the vials did."	Supports using data to develop a claim about what most vials did and what water does generally.

Analysis and findings

Across the investigation, we found that students incorporated resources from multiple representational systems to build and revise explanations of water expansion and the conservation of matter. Further, we identified and described moments when systems *interlocked for students,* in that they came to see these representational systems as bearing on each other; for example by using micro-level information from the simulation to explain the macro-level phenomenon of the bottle breaking. In particular, one mechanism that appeared to support students' use of representations as models and their explicit recognition of these systems as bearing on each other was that of *contradictions.* We found that contradictions surfaced when students recognized gaps in conceptual or representational coherence as resources from different representational systems were combined or put side-by-side. When contradictions were made visible and accessible, they became sites of conceptual innovation as new ideas, questions, and even new contradictions emerged. While not all contradictions co-occur with interlocking models, or were contradictions the only evidence of interlocking models, we found that conceptual progress and meaningful practice could often be mapped to key contradictions. In Table 2, we unpack three contradictions that appeared key to modeling and conceptual progress. How each contradiction emerged and pushed back depended on how student perceived the purpose of the interlocking models. We use one contradiction—how solid water can expand if molecules come together as temperature decreases—to illustrate the emergence and work of contradictions and interlocking models.

Table 2: Overview of the role of contradictions across the investigation

Contradiction	How the contradiction emerged	Opportunities for conceptual innovation
1. How can solid water expand outward as it freezes if molecules slow down and come together as temperature decreases?	In the simulation, students saw water molecules slow down and come together as liquid water decreases in temperature. After watching the bottle breaking video, students thought that water expands as it freezes. Students drew on resources from both representational systems as they constructed their initial models.	Students recognized the contradiction between molecules coming together and water expanding, which highlighted a gap between their current understanding of molecules from the simulation and their perceptual understanding of the bottle breaking. Making sense of the gap led to discussions around different dimensions of size and an investigation to measure weight and water level before and after freezing.
2. How can something take up more space (increase in water level or volume) but still have the same weight?	Students conduct the vials investigation and come to the conclusion that as liquid water freezes, water level increases but weight remains the same. This empirical result conflicted with their perceptual experiences that as something "gets bigger" or takes up more space it also weighs more.	The results of the vial investigation—the weight remains the same but the water level increase in most vials—presented a puzzle. Settling the debate over the results required refining a molecular mechanism for water expansion that accounts for size (molecular arrangement) and weight (number of molecules).
3. How can molecules spread out (to generate pressure on the bottle) but stay together (produce a solid)?	In order to explain the bottle breaking, water must be expanding to put pressure on the bottle. This required a molecular	Students located micro-macro level gap between the molecular model of water molecules spreading out but remaining as a

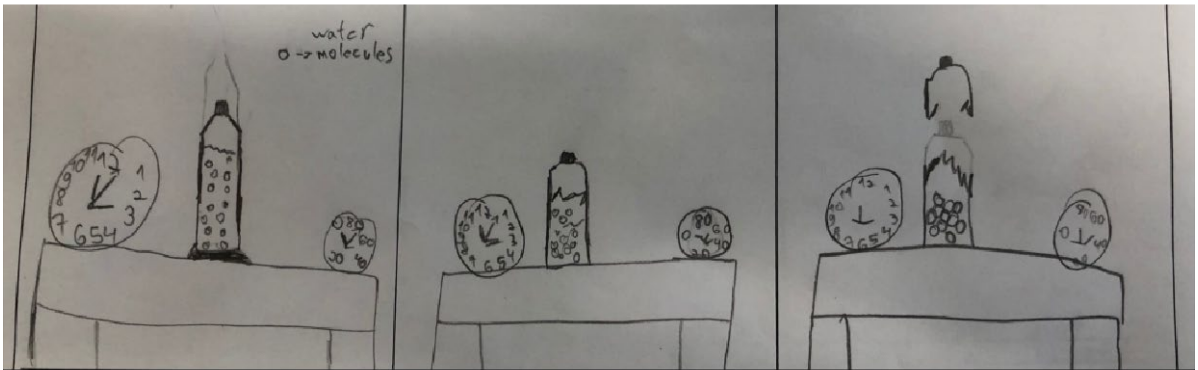
	model of water molecules spreading out as liquid water freezes. This model conflicted with their sensible ideas about solids with molecules tightly packed together.	solid prompted a need to return to the simulation to look closely to what happens to molecules at water's freezing point.

Focal contradiction: How can solid water expand outward as it freezes if molecules slow down and come together as temperature decreases?

One key contradiction that came up over the course of the investigation was between molecular understandings of water and perceptual qualities of water expansion (increases in size, space, or amount). Students who drew on the simulation and earlier class models for how molecules behave as water freezes ran up against a tension in that their molecular understanding—molecules slow down and come together as temperature decreases—aligned with a commonsense understanding of solids (tightly packed, hard, immobile) but could not explain how water expands or creates pressure on the bottle. In the following sections, we illustrate this contradiction as students worked through pencil and paper models before the vial investigation (Figure 1; Points 2 and 3) and as they returned to their initial models to make sense of the results of the vial investigation (Figure 1; Points 4 and 5). We show that this contradiction provided a reoccurring tension at key junctures of the investigation but worked differently based on how and for what purposes models interlocked.

Emergence of the initial contradiction in pencil and paper models

We first consider Roger's (all names pseudonyms) pen and pencil model, developed at the start of the investigation. Students watched the video of the glass bottle breaking, discussed their initial theories, and were asked to draw a model that "showed what happened to the bottle using molecules." Roger's model (Figure 2) indicated a gap between previous models and the bottle breaking that he addressed by including ideas drawn from entities in the video context.



The water is not freezing yet. It is liquid. It is starting to freeze. But the water is warm, and the molecules are spreeding [sic] out. Maybe the energy or the molecules is warm. That is why the molecules are spreeding [sic] out.	The water is more freezed [sic], than the first time. The molecules is getting together, because the water is more colder. And the molecules is slowly and freezing. That happen because the temperature is colder.	The water is totally frozen. And the bottle explode. I think that happened because the lid freezed and there was not space for the cold air to get out. That's why the bottle explode.

Figure 2. Roger's model (handwriting replaced with typeface for legibility).

To develop his model, Roger drew on resources from the video of the bottle breaking, the simulation, and earlier class models. In Frames 1 and 2, we see Roger drawing on ideas from earlier work with the simulation and class models: that molecules come together as water gets colder. His writing is consistent with his drawing, linking water freezing to molecular re-arrangement and a decrease in speed ("getting together" and "slowly"). In Frame 3, Roger continued to show molecules coming together in his drawing, but his written description drew on ideas about cold air and the bottle's lid, from the video.

We see evidence of the simulation and the bottle breaking video interlocking in the Roger's model. In the first two frames, Roger's writing and drawing matched; he drew molecules coming together as the water temperature begins to decrease. In the third frame, he drew molecules packed tightly together as a solid, but then wrote about the bottle breaking because of the lid freezing and "no space" for the air (implicit relation to pressure). The mismatch between his writing and drawing suggest Roger might have understood that molecules coming together cannot fully explain the bottle breaking. Although he was quite sure that this is how molecules behave based on the simulation, in order to complete his model of the bottle breaking he drew on perceptual features of the video—the lid freezing shut, cold air inside the bottle, and lack of space. In short, the contradiction revealed a gap between what he was importing from the simulation and a mechanism for the bottle breaking. Thus, while Roger used molecules as directed and described by the simulation, they were alone not enough to explanation of the bottle breaking.

We see this moment of modeling as a site for conceptual innovation in two ways. For Roger, the search for new resources at the moment of needing an explanation suggested that he might not be satisfied with how his current understandings of molecules can help him construct an explanation. Second, from our point of view as designers and teachers, was that Roger was drawing on molecular arrangements, a resource of the simulation that would be key as we moved into the vial investigation and beyond but was able to sidestep the contradiction we hoped would surface by recruiting an alternative explanation – the air in the bottle needing to get out because the lid exploded. Further, we noted that his molecular arrangement did not correspond with the space that the water took up. Therefore, we chose Roger's model to show the class, wondering if other students would recognize gaps that could lead to further work.

The teacher next projected Roger's model, asked him to explain it, and invited other students to ask clarifying questions and offer critiques. Roger's initially individual model now became a context to collectively reason around the affordances and constraints of one model; with other models (those the students had drawn from themselves) put in contact with this model. While Roger did not yet find his contradiction problematic, other students noticed and probed the contradiction. Casandra asked, "How do the ice gets to the sides [in] the last one?" She noticed the contradiction of molecules coming together and the need of solid water to expand to the sides of the bottle. In addition, her question highlighted the representational need for molecules to represent the edges of water, either as liquid or solid. Her question, and those of other students, implied a need of and mechanism for water expansion not evident in Roger's model. Through her question, Casandra demonstrated how contradictions can elicit questions that surface the need for further explanation. Roger made use of resources from both systems that in turn led to a gap (the arrangement of molecules vs the ice filling the bottle; molecules coming together vs something exploding), community activity around his ideas supported attention to the space that water took up and the fact that the community did not yet have a sufficient model to account for this. This gap subsequently supported a need for the vial investigation (Figure 1; Point 3), in which there was a *reason* to remodel the glass bottle as a simpler system of freezing water measured in height (and weight, which was supported by other model contradictions; Table 1; #2).

<u>Interlocking the contradiction with the vials investigation</u>

After discussing their initial pencil and paper models and turning their attention to the amount or edges of the water, the class tentatively agreed that water "gets bigger" as it freezes and experienced uncertainty about what happened to the weight of the water. We then suggested that they test their ideas, introducing vials that they could fill with water, weigh, and freeze. We further supported them to organize and make claims about the class set of data, developing a consensus claim that "as water freezes, the water level increases but the weight remains the same." At this point, the class had strong empirical evidence that water expands in space but does not increase in weight, but were left with a new puzzle: does it make sense that something could get bigger (water level) but stay the same weight? We revisited three initial models in context with the multiple models we had explore thus far (initial models, the bottle breaking, and vials and consensus claim about water level and weight). We used Roger's model, conjecturing that returning to this model would support conceptual progress, as the representation of molecules coming closer together now contradicted both the bottle breaking video (water expands) and the results of the vial investigation (water level increases). After students considered all three models in small groups, we introduced Roger's model to the whole class with the question: Can this model explain how water expands (gets bigger) when it freezes? In their discussion, students continued to work through the contradiction embedded in Roger's model of the bottle breaking and drew on resources from the vial investigation. During the conversation, one student, Victoria, wondered of Roger's model,

1. Victoria: A lot of people said that they are separating and [expanding], but like we can see in the drawing there they are coming together. So how are they [expanding] and then come together (.) so I am asking=
2. Jackson: =Some people say the water is spread out and (inaudible) but this illustration the water is close together
3. Victoria: That is my question because I don't know if they expanded or came together

While Victoria is not yet directly attending to water level, her question resurfaces the contradiction embedded in Roger's model as a source of tension. As it is taken up by other students, Victoria positioned the contradiction as necessary to resolve before moving forward. The driving question of "Does the model explain how water expands (gets bigger) when it freezes?" was shifted by Victoria, and the students worked to unpack the now further complicated contradiction: How can water molecules come together but water expand? To illustrate, Jackson later responded to Victoria's question, returning to the contradiction and introducing a new mechanism for pressure,

> "the simulation, it was so cold that water molecules and [brings his hands together] and I think it is like this (.) these don't spread out but when the water molecules stay together they make pressure (inaudible) and air molecules don't have the space and the water level up and explode."

We view this moment as a powerful example of interlocking models and the role of contradictions. For Jackson, it is necessary that 1) molecules come together as temperature decreases, as evidenced by the simulation, 2) there must be a mechanism for pressure, as evidenced by the bottle breaking and 3) the water level increases, as evidenced by the vials investigation. All three of these resources are stable enough for Jackson that he introduces them as constraints for an satisfying explanation. In order for these to work together in a plausible explanation, Jackson introduced the idea that pressure on the molecules can explain expansion if you consider air. We consider Jackson's tentative explanation, still in reference to the initial contradiction, evidence that students were moving between the resources of the video, simulation, and the vials. In response, the teacher was able to pivot between representational systems, calling attention to specific aspects or entities to support interlocking models,

1. Teacher: Yes or no (.) does the water level get bigger in this picture (.) so I am going to call on a couple friends to explain their thinking (.) Barry (.) what are you thinking
2. Barry: So that isn't the water level [pointing to the third frame]
3. Teacher: So here yeah the water level what do you see different about the water level in this one
4. Barry: But Roger explained that that was breaking
5. Roger: Something that I need to say is that like the water level of the second one and the third one needed to be bigger than the first one because drew the bottle bigger and the put the water level in the first one higher
6. Teacher: So that's (.) so it seems like that's your thinking now using the information that water level gets bigger that your water level needs to get bigger as well

Through refocusing on a main resource from vials (Line 1), Barry was able to draw on water level and question Roger's model. Barry points out that Roger's "break" was where water level should be located in order to represent water expansion as a mechanism for the bottle breaking. Although Roger's model never intended to show water level increase, he was now held accountable to it in his drawing. Yet, Roger was able to revise his model in the moment, retrofitting water level to his initial drawing as a representational, rather than conceptual, mistake (Line 5). In this episode, the teacher called attention back toward water level, a resource not original to Roger's model, that keyed Barry to press on the contradiction such that Roger could articulate his conceptual understanding and cleverly re-represent the explanation provided by his initial pencil and paper model.

Conclusion and implications

For authentic and epistemically honest modeling to occur in classrooms, designs for practice-based science learning must support students to see models as purposeful contexts for reasoning. This design approach is often discussed in terms of positioning models as tentative or open-ended, in service of scientific practice rather than reaching the canonical answer. Here, we contribute to this literature by explicitly designing in a context where (1) individual representational systems could not fully explain the phenomenon in question and (2) it is the interlocking, or coming together of partial models, that allows students to see models as tentative and incomplete *and* provides a source of conceptual innovation. For example, in our design the representational systems provided resources with different scales and modalities (e.g., the simulation versus the bottle breaking video). Only when these systems interlocked did students find a reason to interrogate the affordances and constraints within and across each representational system in order to develop an explanation of water expansion that made the law of conservation of matter useful.

In our analysis, we sought to understand how models came to interlock for students. We highlighted one mechanism, that of contradictions, that supported students to relate different forms of conceptual and representational information through the development and use of interlocking models. Following Roger's model across the introduction of new representational systems, we showed how contradictions emerged and came to hold interlocking models together. In Roger's initial pencil and paper model, he drew on resources from the simulation and video of the bottle breaking. However, these resources did not come to bear on each other until the contradiction (molecules coming together as water cooled vs moving apart to make the water push on the bottle) surfaced during whole class discussion. With the contradiction now a focus of activity, students questioned the relationships between representations and highlighted gaps in their collective understanding of the phenomenon. We found when these contradictions provided students with pushback, interlocking models emerged *for students* and did work to support conceptual innovation and meaningful practice. In our example, students were able to re-interrogate the contradiction of Roger's model with new assumptions based on the results of the vial investigation. As the contradiction resurfaced for students, it came with new puzzles and problems thus driving a need for iteration and further modeling. This analysis highlights how interlocking models might serve as a productive design tool to support students' meaningful modeling (Berland et al, 2016). It reveals key mechanisms that foreground relationships between representational systems (in this case contradictions). Supporting models to interlock from the students' perspective appears to provide the sort of flexibility and purpose we hope to see in emergent modeling practices as well as in a classroom modeling enterprise.

Teacher Learning From Implementing an Instructional Design for Literary Argumentation

Allison H. Hall, Learning Sciences Research Institute, University of Illinois at Chicago, ahall33@uic.edu
Susan R. Goldman, Learning Sciences Research Institute, University of Illinois at Chicago, sgoldman@uic.edu

Abstract: This paper reports a case study of an 11th grade English teacher's learning through participation in design-based research intended to support students in literary argumentation. Literary argumentation requires that students develop criteria for thematic concepts as common ground for interpretation and discussion of texts. This study examines two components of instruction around the generation of criteria from the first and third years of a design-based research project to understand what the teacher learned from the implementation of a designed 9-week unit and how it informed her iterative design and enactment of a year-long curriculum. Findings showed marked differences in her design across iterations, including in the choice of themes and texts, task and participation structures, and foci of inquiry. The connection between the criteria-building work students did and their subsequent work was also notably different.

Introduction

Research has shown that teacher involvement in design of instructional materials and tasks provides a context for teacher learning and professional development, especially during iterative cycles of design as is the case in design-based research (DBR) (Kyza & Nicolaidou, 2016; Penuel & Gallagher, 2009; Voogt et al., 2015). To date however, there are few analyses of teachers learning through the process of iterative design of instructional units. Our work with teachers during a multi-year design-based research project (Project READI, Goldman et al., 2010) provided a context in which to study what and how teachers learned as they participated in this process. In this paper, we focus on the case of one high school literature teacher, Ms. Edwards, who participated in multiple design cycles over a three-year period. We examine what she learned and the mechanisms supporting that learning.

Designing instruction requires clear explication of the knowledge and practices students are expected to learn and an understanding of how to structure learning experiences to support them in meeting those expectations. Learning experiences encompass the type and structure of tasks, as well as how they are sequenced and coordinated (Kang, et al., 2016). They are critical determiners of the intellectual work and classroom discourse in which students engage (Jackson, et al., 2013; Stein & Lane, 1996). Clear explication of learning goals for students depends on a conceptual analysis of the discipline in which the learning is to occur, in this case literary argumentation. Literary argumentation requires that readers move beyond the literal words and surface meaning of the text to explore deeper meanings (Graves & Frederiksen, 1991; Zeitz, 1994). Interpretations of literary texts are expected to vary as each reader brings their own background knowledge, life experiences, and personal beliefs to the text, but these interpretations still must be based on and bounded by the text (Lee et al., 2016). This variation in interpretation provides fertile ground for argumentation, in which the validity of claims depends on the warrants used to explain the connection between what is in the text and the interpretation. Warrants are drawn from knowledge and experiences readers bring to the literary work, including criteria for various character traits (e.g., heroism, honesty) and overall story themes (e.g., coming of age, identity, gender and power). For example, to argue that Luke Skywalker is heroic depends on understanding the features or characteristics that constitute "hero-hood" and heroic action and using such knowledge to identify parts of the text that provide evidence of those criteria. An important component of instruction that prepares students to engage in literary argumentation, especially the reasoning that warrants claims they make, is establishing criteria for making inferences about characters and themes in literary texts.

What criteria need to be established is dependent on the specific texts and tasks (e.g., character traits, thematic claims) that are the instructional focus. Design work thus begins with close analysis of the texts and the literary problems or interpretive puzzles they pose (Lee et al, 2016; Rainey, 2017). Literary problems are questions about the text that can be answered in various ways, such as "Is this character a hero?" or "Which character has more power?" The interpretive problems identified through such analyses bring to light the criteria students will need to draw on to make interpretive arguments about themes and characters. This information can then guide the design of activities intended to build such knowledge through tasks that tap into the life experiences of the students. One way to do this is to provide students with relatively brief scenarios of everyday life or accessible texts that are culturally familiar (e.g., song lyrics, comics, advertisements). Based on these texts, students are asked to develop criteria for identifying and characterizing a concept, trait, or theme by interrogating familiar contexts that portray aspects of those concepts, traits, or themes (McCann, 2003; Smagorinsky et al., 1987).

Developing criteria around abstract themes with more accessible texts can support students in both identifying and developing thematic interpretations of more complex works (Smith & Hillocks, 1988).

The case study of teacher learning reported in this paper focuses on the design of the criteria building component as related to the themes, texts, and tasks of literary argumentation units designed and implemented over a three-year period by Ms. Edwards. The research questions the case addresses are: *What did the teacher learn from initial implementation that informed the redesign in years 2 and 3, particularly of the criteria building component? How and why did that learning inform revisions to the design?*

Case context

Ms. Edwards taught 11th grade English in a large urban high school serving a diverse student population (47.9% Black, 43.1% Hispanic, 3.8% White, 1.9% Asian, and 3.3% mixed race; 87% free and reduced lunch). As a White teacher in this setting, she was particularly mindful of the importance of drawing on students' experiences outside the classroom and preparing them to pursue their goals beyond high school. She had been teaching for two years when she volunteered to participate in Project READI as part of the literature design team (Goldman et al., 2016).

Ms. Edwards three-year participation in Project READI starting in spring 2013 involved working closely with researchers to iteratively design and implement instruction supporting students in literary analysis and evidence-based argumentation. In Year 1, she implemented a nine-week unit on the theme *coming of age* as reflected in several short stories. This unit was chiefly designed by researchers as an iteration of units implemented in other contexts. In Year 2, she designed a sequence of units focused on the themes of *gender and power* as manifest in two major novels and using shorter texts to build criteria and background knowledge relevant to the context of the novels. This design then underwent minor revisions that were implemented in Year 3. During her time on the project, Ms. Edwards also participated in bi-weekly meetings with the design team, which consisted of researchers and other teachers, and quarterly cross-disciplinary professional development sessions. Three years later, she joined us on a new project focused on teacher learning, providing opportunities for Ms. Edwards and READI researchers to analyze and reflect on her classroom videos and learning experiences from Project READI. (How Teachers learn: Orchestrating Disciplinary Discourse, Goldman, et al., 2018). (See Figure 1.)

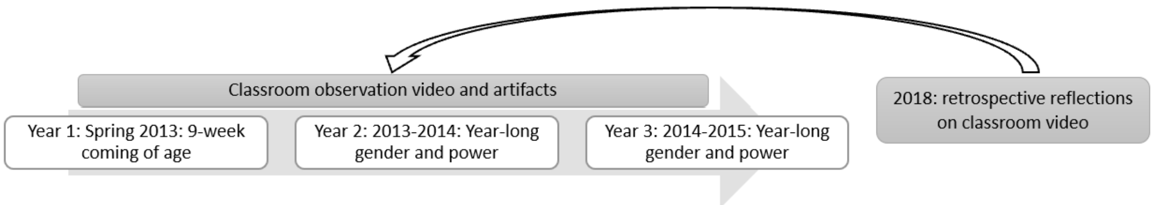

Figure 1. Timeline of Ms. Edwards' participation and data collection.

For the analysis presented here, we focused on criteria building components of literary interpretation as designed and implemented across Years 1, 2, and 3. During the implementation of the first- and third-year units, researchers were in the classrooms almost every day collecting observation data (video and field notes) and debriefing with the teacher after class. During Year 2, the teacher kept a journal documenting implementation and her reflections on it with only occasional classroom observations by researchers.

Data sources for this study are teacher written reflections, researcher analytic memos, and reflective conversations during and after implementations as well as teacher and researcher retrospective reflections on video and field notes from classroom observations (35 from year one, 12 from year two, 111 from year three).

Analytic approach

In the first phase of analysis, we did repeated readings and content analysis of the reflections, analytic memos, and conversations with the teacher. The criteria-building component of the design emerged as a central focus of the teacher's redesign, necessitated by changes to the theme and literary texts that were the backbone of the instructional units. Therefore, we examined additional data sources to identify what changed and evidence for why and how it changed. We segmented each criteria-building component based on changes in the focus of the inquiry or in participation structure (whole class, small group, individual) and characterized each segment according to the nature of activities (reading, discussion, writing, etc.), participation structures, texts and materials, and length of time spent. This gave us a view of the structural similarities and differences in the two years. After that, we used content analysis and repeated readings of transcripts and field notes to identify themes in terms of the instructional design, paying particular attention to how criteria were introduced, the role of students in developing the criteria, the task set-ups (instructions and prompts), how criteria were used in class activities, and the type of support provided by the teacher. We also traced where and how the criteria were invoked in subsequent components of the overall unit. Finally, we returned to the reflections, analytic memos, and conversations with the teacher for evidence of why the teacher revised the design and implementation in the ways she did.

Findings

Based on the implementation of the first, 9-week instructional unit, Ms. Edwards made changes to the theme, literary texts, and tasks that were the focus of the instructional units for the Year 2 implementation. We first consider why the change in focus. We then closely examine what changed in the redesign of the criteria building component. We conclude with examining the how and why of the criteria building redesign and its impact on students' literary interpretation.

Change in choice of themes and texts

One of the more fundamental changes that Ms. Edwards made in designing the year-long curriculum was in the themes. Specifically, she decided to focus on criteria for gender and power instead of coming of age. Although coming of age is a common theme in literary texts, it may not have been as flexible for the variety of texts Ms. Edwards wanted to have students read. She also indicated that during the Year 1 iteration, she felt students lacked interest in the coming of age theme. Indeed, coming of age texts are often recommended for middle school students who are more squarely in the throes of puberty and other changes that generally accompany "coming of age." Her students were 16-17 years old on average and likely looking more towards their adult futures.

The decision to change the theme, specifically to gender and power, was based on the teacher's belief that these themes were both relevant and important for her students to explore, as she indicated:

> "They know the themes of friendship and that kind of thing, but then to scale that out and make literature a way they look at and learn about the world […] This matters more than just this class, but it matters to your world and the way your world looks, in a way that makes them think about some ways the world might not work very well, because I don't think they very often get to do that."

Ms. Edwards' response suggests that she purposefully chose the themes to give students opportunities to learn ways to see and understand the significant roles that gender and power play not only in literature, but also in their own lives and in the world around them. Her reasoning aligns with the epistemic purpose of reading literature as a means of understanding the human condition (Lee et al. 2016).

Choosing to change thematic focus accompanied her choice to use different texts. She chose themes that she could build a year-long curriculum around, using two novels as the focal texts as compared to the short stories used in the nine-week unit. In fact, in designing the year-long curriculum, she chose to use texts that she was familiar with and had taught before. In describing the difference between her teaching one of the novels before and after designing and implementing the first nine-week unit, she said "My practice moved from attention to plot and asking students to make surface connections to characters to attention to language and the way in which it helps the reader to understand characters, theme, etc." Her choice of texts was also ambitious in the later iterations as one of the novels she chose was traditionally used in university level literature classes. In her reflective interviews, she recognized that the complexity of her design was in fact enabled by her experience implementing the first nine-week unit. She explained,

> "How needed it was to have those texts and structures and ways of doing in that 9-week module, how necessary it was to engage in those and have the chance to think about them and reflect on them, and how I might have gotten lost in what I was trying to do had I just tried to superimpose that thinking on what I had already been doing. I think being deep in that work and reflecting on it, and then saying what have I learned and how do I lift that onto a curriculum that is this year-long study of power?"

Having the opportunity to implement the 9-week unit and reflect on it showed her that the work in an English classroom could be fundamentally different from the traditional focus on text comprehension. She realized the need to completely upend the way that she had been teaching, which included generating new designs for the criteria-building piece based on concepts she anticipated students would need to analyze and interpret the novels.

Redesign of the criteria-building component

Ms. Edwards used the same overall three-phase structure that was part of the 9-week unit in the criteria building component for her year-long curriculum: 1) introducing the concepts and generating initial criteria by relating to students' own personal experiences, 2) providing students with everyday situations from which to further develop and apply the criteria, and 3) having students produce a written argument involving use of the criteria. However, there were marked differences in the designs and implementations of each phase of the criteria building component across the three years, including differences in the choice of themes and texts, foci of inquiry, and opportunities to consider various examples of criteria, all of which impacted the use of criteria during the remainder of the units.

Faced with how to prepare students to probe more complex themes in more complex texts, Ms. Edwards had to reflect on what had worked or not during the first implementation and consider that in terms of the new themes. In the first unit, the teacher had introduced the idea of coming of age by asking students in the context of a whole class discussion if they thought that they themselves had come of age and what they thought it meant to come of age. She started a public list of criteria and characteristics that students came up with for coming of age, which was added to during discussion of four scenarios that featured coming of age. Each scenario presented a brief description of a situation that adolescents might find themselves in and the reactions of characters to those situations. For example, the first scenario was about an adolescent girl:

> "Right around the time she turns fourteen, Hillary begins to see her neighbor, who is also fourteen, not just as someone to chase in the streets and make fun of, but someone that she thinks is cute. One day, they are both sitting on her front stoop, watching the cars pass by. Without even really knowing what she is doing, she leans over and kisses him."

Each scenario was followed by three prompts: 1) Has the character come of age? 2) Why or why not? 3) Define coming of age based on your explanation. The first scenario was read and discussed through a teacher-led whole class discussion. That discussion continued the second day and was followed by students working through the rest of the scenarios together with partners or in small groups. These discussions generated a list of criteria that the teacher kept on the wall of the classroom (Figure 2). For the culminating task, students were to decide which criteria was the strongest using the scenarios as evidence. The template provided academic language and sentence structures intended help students express their ideas. The specific instructions were

> "So, you are taking two scenarios and two criteria for coming of age and you're saying: I see that this character and this scenario, you can make some argument about whether they have or haven't come of age based on this criteria [...] I also see that this character and this criteria show a coming of age and I think this is stronger and I am going to use this template to help me make that argument."

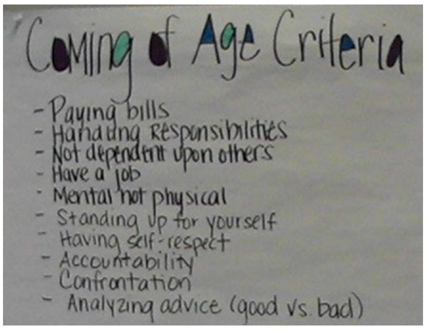

Figure 2. Criteria for coming of age.

These templates were handed in the next day and not discussed further.

Reflections, conversations, and memos around this initial implementation revealed several issues with this design. First was that the scenarios were not ideal for supporting the development of criteria for coming of age. Perhaps evident in the example above, the scenarios were sometimes too literal or obvious to generate much discussion. In addition, students seemed hard-pressed to "define" what it meant to come of age from the scenarios. Coming of age stories typically trace a character across time and emphasize the changes in that character. These scenarios were too brief to be able to see the transformation in a character and so did not lend themselves to developing an understanding of the types of things an author would use to signal coming of age in a character. The difficulties that students had in combination with Ms. Edwards' desire for them to deal with more complex themes prompted her to make several changes to the design in the following years.

Similar to the first iteration, the teacher introduced the thematic concepts for the unit, gender and power, by connecting to students' personal experiences. However, instead of asking what gender and power mean, she had students make a t-chart with one column labeled "men have more power than women" and the other "women have more power than men." She told them to base their ideas on "the world as we know it" and list at least ten criteria on each side of the chart. The teacher modeled phrasing of criteria using an example from a previous class period ("men have the ability to physically intimidate") and then let students work with groups or partners to further fill out their lists. She asked them to "critically think about the ways in our society in which men are more powerful than women and women are more powerful than men." Students continued to work on their lists of criteria independently for homework. The following day these criteria were discussed and as in year 1, a public list was kept (Figure 3).

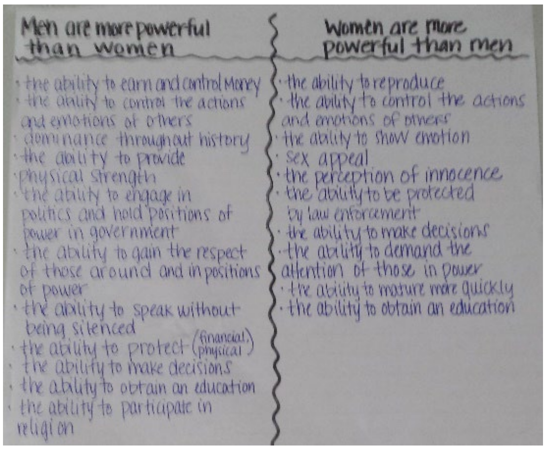

Figure 3. Criteria for gender and power.

These criteria-building tasks generated more and a different type of criteria than in Year 1. This is in part because in Year 1, the primary task was to "define" coming of age, while in Year 3, the teacher set up discussions of gender and power as an argument: "We are going to take each side of this argument and develop criteria for what it looks like when men have more power than women and women have more power than men." By referring to these lists of criteria as sides of an argument, she was emphasizing the idea that the criteria themselves were debatable and negotiable.

Instructional time spent on the criteria-building component was longer than in Year 1 (1.5 lessons in Year 1 versus 2.5 in Year 2) and there were more opportunities for students to practice applying the criteria to different texts after the initial criteria-building exercises. In Year 1, students were not given any opportunity to practice with texts other than during the criteria-building lesson in which a list of criteria were generated. However, in Year 3, Ms. Edwards gave the students more practice in both application and in developing arguments both orally and in writing using a variety of images. That is, after generating the initial list of criteria, Ms. Edwards put four images up on the screen (a crown, a pile of money, a silhouette of a man in a suit, and a stylized image of a muscular body) and asked the students independently to choose one and "in three sentences write why this image connects to or corresponds to power." Students then had time to discuss in small groups the image they chose and what it said about power. This was followed by a whole group discussion of what students thought of the images and how they represented power. The teacher added to the public list of criteria as they discussed. This discussion was interrupted by the bell and picked up at the beginning of class the third day. Then the rest of the lesson on the third day focused on the two images shown in Figure 4.

Figure 4a. Image used to discuss power and gender. Figure 4b. *American Girl in Italy*, 1951, by Ruth Orkin.

The first image, the one of the man with tape over his mouth (Figure 4a), was shown on the screen and used as the basis for discussion. The teacher told students: "I want you to talk about whether the person in this image is powerful or powerless. And when you have that discussion, what I need you to do is refer back to that criteria. So what criteria are you using to say he is either powerful or powerless?" A whole class discussion followed during which the idea that the same evidence could be used to support two different claims surfaced. The second image (Figure 4b, a famous photograph of a woman walking down the street in 1950s Italy) was used to further elaborate how to support interpretive claims with criteria, evidence, and reasoning. The teacher had students discuss the photograph briefly and then independently write a claim as to whether the men or the woman in the photograph had power. Then she had them work together in small groups or with partners to compile evidence from the photograph to support those claims. Lastly, they were to help each other label each piece of evidence with the criteria for power they were using. Toward the end of class, students shared their thinking about the photograph in a whole class discussion. Compared to Year 1, these activities gave students many more opportunities to practice both orally and in writing with varying participation structures and texts.

Another revision from Year 1 was in the culminating writing task. Although in both years the teacher asked the students to produce a written argument as the culminating task for the criteria-building components of instruction, in Year 1, students were simply asked to write an argument about which criteria was strongest, without a particular context to apply it to. In Year 3, the writing task was more involved:

> "For the first paragraph you are going to make a claim, provide evidence and reasoning for the idea that the woman in this picture is in power […] And remember that tape on the mouth, right? Our argument lives or dies in our explanation and our reasoning, so how can you take that piece of evidence and explain to your reader how that evidence proves to you that the woman is in power [...] Your second paragraph is going to take the opposite stance. You are going to make the claim that the men in this image are in power. You are going to provide

> evidence to support that and you are going to provide your reasoning."

The Year 3 written arguments and the possibility of the same evidence being used to argue two different sides were the subject of further discussion in the subsequent class, at the end of which students were given the option to revise their writing. These writing assignments for each year underscore the difference in what students were being asked to do with the thematic criteria. In the later iteration, students were asked to make claims about characters, the woman or men, in the photograph having power and then support those claims with specific evidence, criteria, and reasoning. They also had to argue both sides, drawing attention to the importance in crafting arguments of how criteria, evidence, and reasoning are used to support varying claims. This type of complex reasoning and argumentation was setting the students up for the work Ms. Edwards expected them to do with the longer, more complex texts that were the focus of the units.

Reflecting on implementation: The how and why of teacher learning

Ms. Edwards' revisions to the units implemented were substantial from the initial 9-week unit to the year-long design. These changes can be attributed not only to her decision to change the theme and texts but also to what she noticed in the work that students did during the first implementation. Her written reflections throughout that implementation revealed the extent to which students struggled with using the criteria when they analyzed longer, more complex literary texts. This was the case even though coming of age was a less complex theme. In referring to a Year 1 class discussion about a story in which an adolescent girl in a rage ripped up a neighbor's cherished flowers, Ms. Edwards wrote:

> "Students were successful in determining this moment of the ripping up of the flowers as her coming of age but needed prompting to think through the criteria used to determine this as a coming of age moment"

Ms. Edwards recognized that students did not have a sufficiently robust understanding of coming of age to apply the criteria developed earlier in the unit to a longer story that occurred toward the end of the 9-week unit. She attributed this in part to not having spent enough time on developing and practicing use of the criteria across a range of texts. This led to designing the criteria-building components in subsequent iterations (Years 2 and 3) to include more time and more practice with varying texts, participation structures, and combinations of writing and discussing. In the reflective conversations, the teacher mentioned the importance of giving students an opportunity to write down their thoughts individually before discussing. In one reflection, she noted, "I do think the opportunity for them to write first was important for the discussion that came after." In the Year 2 and 3 iterations, she also saw as beneficial giving students various ways to participate and interact with content, especially for those students who were uncomfortable participating in whole class discussions:

> "I just keep going back to those voices that were quiet. And with the built-in support of writing first and the built-in support of a partner conversation, I think I could have drawn on them because they had those supports. I feel uncomfortable calling on a child without giving them those supports. But because they had the time to write and think and because they had the time to have a partner conversation, it would have been a good move to call out those voices that were silent because they had the support."

These reflections indicate that her movement towards varying participation and task structures was a purposeful choice in the way she implemented the later designs.

Her students' struggle also encouraged her to reflect on what she was learning about her own literary interpretive practices. In reflecting on her experiences, she said, "I realized I wasn't apprenticing them into any of the ways I paid attention to literature." This realization led her to think about how to introduce and support students in those practices rather than on comprehension and character traits, a typical focus of English classes and what her students had gravitated toward in the first iteration. The first 9-week unit provided opportunities to see first-hand what students needed to meaningfully build criteria that were sufficiently robust to support their argumentation in lengthier and more complex texts. One aspect of the design that she knew would help in this support was greater purposefulness and coherence of instruction leading from the criteria-building to the work in the rest of the unit. In Year 1, criteria development focused on whether a character had come of age and on developing a definition of such. Thus, it was not surprising that students ignored the criteria or struggled to use them when interpreting the short stories in the latter part of the unit. For example, the use of coming of age criteria in the following task instructions from the latter part of the unit was unfamiliar:

> "You are going to talk with one person recording: Has the character come of age? Why or why not? Do you view this coming of age as positive or negative? And then you are going to say, 'Ok, I think the character has or hasn't come of age. I think this is positive or negative.' But then you have to go back into the text and say: What does the author think? Does the author think the character has come of age? And how do you know? And then does the author believe this is positive or does the author believe this is negative?"

These questions go beyond simply asking for the theme and applying its definition. This task asks students to analyze the language and structure of the text to make judgments about the author's intentions. This type of task certainly is the work of literary analysis; however, the only prior work specifically with the theme of coming of age was the work during that initial criteria-building. Students were not equipped to go beyond the questions around whether characters had come of age and this likely explains even further why students struggled with these tasks. The teacher wrote the following in her reflections during the implementation:

> "We asked students to think through how the symbol of the marigolds informs our thinking about the main character's coming of age. Students were entirely confused by this."

This led to the teacher having to scaffold students' analyses and arguments to a much greater extent than she had planned, taking two whole lessons to walk through the connection between the language the author used and the theme in the text. Her reflections during the unit repeatedly remarked on how she had spent more time on certain instructional activities than planned. These experiences contributed to redesign decisions about how much time to spend on criteria-building, the necessity of providing various and repeated opportunities to use themes for interpretive purposes, and the need for coherence in the focus of the interpretive problems presented to students.

Unlike in Year 1, the focus of the inquiry throughout the third year followed directly from the way the students had been introduced to the criteria for gender and power, emphasizing the complexity of analyzing texts for these themes and developing strong arguments to support their claims with both textual evidence and criteria. As an ongoing assignment, students kept "critical reading journals," which consisted of quotations from the text followed by three to four sentences analyzing the significance of the quotation in relation to a theme (e.g., What does this passage tell you about gender and power?). The classroom discussions and writing assignments were also often focused on the way gender and power played out among the characters in the various texts. The teacher's struggles with getting students to attend to theme during the first iteration helped her recognize the importance of designing her instruction in a way that allowed the themes to be woven through the texts and tasks throughout the year. The criteria-building set students up to engage deeply and repeatedly with the complexities of gender and power among characters in various texts, hotly debating both their claims and the criteria throughout the year.

Discussion and implications

The case of Ms. Edwards provides a glimpse into the processes involved in teacher learning that can occur in the context of participation in iterative design-based research. The work adds to unpacking *reflection* and *enactment* as two central mechanisms driving teachers' learning and change as proposed by Clarke and Hollingsworth (2002). Ms. Edwards began the project by enacting a designed module that acted as external input to the knowledge, beliefs, and attitudes she brought to the work. The enactment provided feedback on salient outcomes for students: what students were and were not engaging with as well as what they did or did not find problematic. Reflecting on these outcomes on her own and in interaction with researchers supported her restructuring and refining her design decisions in subsequent iterations. The iterations allowed her to practice new ways of engaging students in the intellectual work and thus providing feedback on the design rationale that had driven the changes. The importance of feedback with opportunities to practice is one of the oldest principles of learning in psychology (Thorndike, 1913). This case is a situated manifestation of its relevance to classroom teaching and learning.

The design-based research context provided opportunities not only for external input that set the stage for enactment but opportunities for external perspectives on salient outcomes, joint reflection on their import, and knowledge building about what was needed to support students in the complex work of literary interpretation. These experiences of enactment and reflection inside the process of design-based research helped Ms. Edwards imagine the myriad potentials and possibilities for re-designing instruction in her classroom. In addition, Ms. Edwards' involvement in the larger project's various learning contexts (teacher-researcher relationship, design team meetings, cross-disciplinary professional development meetings) provided multiple opportunities for her to examine and deepen her knowledge of her own literary processes. The increased metacognitive awareness of her own literary interpretation practices reshaped her lens on how she wanted her students to engage with literary works to create warranted literary arguments. Armed with this altered understanding of student learning goals, Ms. Edwards was able to redesign using the underlying principles of the initial module and create activities that supported students in wrestling with complex themes and literary works.

Thus, the redesign of the themes, selection of literary works, and the criteria building sequences could be traced to her own professional learning regarding literary interpretation and argumentation and to feedback from students' engagement and challenges in building criteria for literary argumentation. Researchers engaging collaboratively with teachers in this type of design-based research created opportunities for teaching and learning processes that are unlikely to have occurred had teachers been handed designed curricula to implement, even with high quality professional development intended to prepare them to use the curricula. Thus, this case provides practice-based evidence of the value of iterative cycles of collaborative co-design among teachers and researchers.
