## Abstract

Emerging Zoned Namespace (ZNS) SSDs, providing the coarse-grained zone abstraction, hold the potential to significantly boost the cost-efficiency of future storage infrastructure and mitigate performance unpredictability. However, existing ZNS SSDs have a static zoned interface, making them in-adaptable to workload runtime behavior, unscalable to underlying hardware capabilities, and interfering with co-located zones. Applications either under-provision the zone resources yielding unsatisfied throughput, create over-provisioned zones that squander the cost, or experience unexpected I/O latencies.

We propose eZNS, an elastic zoned namespace interface that exposes an identical zone with predictable characteristics. eZNS comprises two major components: a zone arbiter that manages zone allocation and active resources on the control-plane; a hierarchical I/O scheduler with read congestion control and write admission control on the data-plane. Together, eZNS enables the transparent use of a ZNS SSD and closes the gap between application requirements and zone interface properties. Our evaluations over RocksDB demonstrate that eZNS outperforms a static zoned interface by 17.7% and 80.3% in throughput and tail latency, respectively, at most.

## 1 Introduction

The NVMe Zoned Namespace (ZNS) is a newly-introduced storage interface and has received enormous attention from data center and enterprise storage vendors. By dividing the SSD physical address space into logical zones, migrating from device-side implicit garbage collection (GC) to host-side explicit reclaim, and eradicating random write accesses, a ZNS SSD significantly reduces device DRAM needs, resolves the write amplification (WAF) issue, minimizes costly over-provisioning, and mitigates I/O interference. However, the performance characteristics of the ZNS interface are not well-understood. In particular, to build efficient I/O stacks over it, we should be cognizant of (1) how the underlying SSD exposes the zone interface and enforces its execution restrictions; (2) what trade-offs the device’s internal mechanisms make to balance between cost and performance. For

example, the device-enforced zone placement makes the actual I/O bandwidth capacity of a zone contingent on how a ZNS SSD allocates zone blocks across channels/dies. Further, a zone is not a performance-isolated domain, and one could observe considerable I/O interference for inter-zone read and write requests. Therefore, there is a strong need to understand its idiosyncratic features and bring enough clarity to host storage applications.

We perform a detailed performance characterization of a commodity ZNS SSD, investigate its device-internal mechanisms, and analyze the benefits and pitfalls under different I/O profiles in both standalone and co-located scenarios. Using carefully calibrated microbenchmarks, we examine the interaction between zones and the underlying SSD from three perspectives: zone striping, zone allocation, and zone interference. We also compare with conventional SSDs when necessary to investigate the peculiarity of a ZNS SSD. Our experiments highlight the interface’s capabilities to mitigate the burden on I/O spatial and temporal management, identify constraints that would cause sub-optimal performance, and provide guidance on overcoming the limitations.

We then propose eZNS, a new interface layer, which provides a device-agnostic zoned namespace to the host system, mitigates inter-/intra-zone interference, and improves the device bandwidth by allocating active resources based on the application workload profile. eZNS is transparent to upper-layer applications and storage stacks. Specifically, eZNS comprises two components: the zone arbiter on the control plane and a tenant-cognizant I/O scheduler on the data plane. The zone arbiter maintains the device shadow view that manages zone allocations and realizes a dynamic resource allocation by a zone ballooning mechanism. It allows serving applications to max out the device capability by enabling the maximum device parallelism given the workload profile and rebalancing inactive bandwidth across namespaces. The I/O scheduler of eZNS leverages the intrinsic characteristics of ZNS, where there are no hardware-hidden internal bookkeeping operations. Read I/Os become more predictable, and one can directly harness this property to examine inter-zone interference.

Figure 1: The architecture of a conventional and ZNS SSD.

On the other hand, write I/Os share a performance domain due to the write cache architecture of the SSD, causing global congestion across all active zones. eZNS, therefore, applies a local congestion control for reads and a global admission control for writes. Our I/O schedulers mitigate the interference independently but improve overall system performance cooperatively. We demonstrate benefits in the evaluation (§5) over micro-benchmarks and RocksDB.

## 2 Background and Motivation

This section reviews the basics of NAND-based SSDs, introduces the ZNS SSD and its features, and discusses the problems with the existing zoned interface.

### 2.1 NAND-based SSDs

A NAND-based SSD combines an array of flash memory dies and is able to deliver a bandwidth of several GB/s. It comprises four main architectural components (Figure 1): (1) a host interface logic (HIL) that implements the protocol used to communicate with the host, such as SCSI [40] and recent NVMe [29]; (2) an SSD controller, enclosing an embedded processor and a flash channel controller, which is responsible for the address translation and scheduling, as well as flash memory management; (3) onboard DRAM, buffering transmitted I/O data and metadata, storing the address translation table, and providing a write cache; (4) a multi-channel subsystem that connects NAND dies via a high-bandwidth interconnect. As shown in Figure 1, a NAND *die* consists of hundreds of *erase blocks*, where each *block* contains hundreds to thousands of *pages*. Each channel holds multiple dies to increase I/O parallelism and bandwidth. Each page encloses a fixed-sized data region and a metadata area that stores ECC and other information. Flash memory supports three major operations: *read*, *program*, and *erase*. The access granularity of a read/program is a page, while the erase command is performed in units of blocks. NAND flash memory has three unique characteristics [1, 10, 12, 19, 26]: (1) no in-place update, where the whole block must be erased before updating any page in that block; (2) asymmetric performance between reads and programs; (3) limited lifetime (endurance) – each cell has a finite number of program/erase (P/E) cycles [22].

To effectively use the NAND flash and address its limitations, SSDs employ a special mapping layer called the flash translation layer (FTL). It provides three major functionalities [13, 20, 33, 52]: (1) dynamically mapping logical block addresses (LBA) to physical NAND pages addresses (PPA); (2) implementing a garbage collection (GC) mechanism to

handle the no in-place update issue and asynchronously reclaim invalid pages; (3) applying a wear-leveling technique to evenly balance the usage (or aging property) of all blocks and prolong the SSD lifespan. However, FTL brings in considerable overheads. First, the translation table requires a large amount of DRAM to store the mapping entries, e.g., 1GB for 1TB NAND capacity for 4KB data unit size. Second, when serving a user I/O, the compounding effect of GC and wear-leveling would trigger additional SSD internal writes (i.e., copying valid pages to erase the block) and lead to the WAF (Write Amplification Factor) problem. Third, the FTL does not employ performance isolation mechanisms and incurs significant interference issues under mixed I/O profiles [28, 32].

### 2.2 Zoned Namespace SSDs

ZNS SSDs, a successor to Open-Channel(OC) SSDs [6, 9], have recently been developed to overcome the aforementioned limitations of conventional SSDs. There are several commodity ZNS SSDs from various vendors [34, 37, 38, 50]. A ZNS SSD applies the same architecture as a conventional one (Figure 1) but exposes the zoned namespace interface. A namespace is a separate logical block address space, like a traditional disk partition, but managed by the NVMe device controller rather than the host software. The device may control the internal block allocation of namespaces to optimize the performance based on the device-specific architecture. In ZNS SSD, the namespace comprises multiple zones instead of blocks in the conventional one, and each namespace owns dedicated *active resources* that are used to open and write a zone.

A ZNS SSD divides the logical address space of namespaces into fixed-sized zones, where each one is a collection of erase blocks and must be written sequentially and reset explicitly. ZNS SSDs present three benefits: (1) Maintain coarse-grained mappings between zones and flash blocks and apply wear-leveling at the zone granularity, requiring much smaller internal DRAM; (2) Eliminate the device-side GC and reclaim NAND blocks via explicit zone resets by host applications, which mitigates the WAF and log-on-log [51] issues and minimizes the over-provisioning overhead; (3) Enable the placement of opened zones across different device channels and dies, providing isolated I/O bandwidth and eliminating inter-zone write interference.

A zone has six states (i.e., *empty*, *implicitly open*, *explicitly open*, *closed*, *full*, *read only*, and *offline*). State transitions are triggered by either write I/Os or zone management commands (i.e., RESET, OPEN, CLOSE, and FINISH). A zone must be opened before issuing writes, but it is capable of serving reads in any state except the *offline* state. *closed* and *open* (both implicit and explicit) are *active* states that require the device to maintain NAND metadata for incoming user write I/Os, limiting the maximum number of active zones. SSDs employ the write cache in DRAM to align the wide range of user I/O sizes to the NAND program unit and comply with the NAND-

specific requirements (timings and program order). In case of a sudden power-off failure, the device flushes uncommitted data in the cache using batteries or capacitors as an emergency power source [46, 54]. Since active zones must have a buffer backed by energy devices for at least one NAND program unit in the cache, the maximum number of active zones is also constrained by the size of the write cache.

A zone provides three I/O commands: *read*, *sequential write*, and *append*. The *append* works similarly to the nameless write [53] but improves the host I/O efficiency rather than the internal NAND page allocation. Compared with the normal write, a zone *append* command does not specify the LBA in the I/O submission request, whilst the SSD will determine it at processing time and return the address in the response. Thus, user applications can submit multiple outstanding operations simultaneously without violating the restriction of sequential writes. Random writes are disallowed on ZNS SSDs, and the zone is erased as a whole (via the RESET). A ZNS SSD delegates the FTL and GC responsibilities to user applications, where they are performed at the zone granularity, thus eliminating traditional SSD overheads.

### 2.3 Small-zone and Large-zone ZNS SSDs

Zones can be classified into two types: *physical zone* and *logical zone*. Physical zones are the smallest unit of zone allocation and consist of one or more erasure blocks on a single die. They are device-backed and offer fine-grained control over storage resources. In contrast, logical zones refer to a striped zone region consisting of multiple physical zones. They can be implemented by either the device firmware or application and provide higher bandwidth through striping. Large-zone ZNS SSDs provide coarse-grained large logical zones with a fixed striping configuration that spans multiple dies across all internal channels but offers less freedom for controlling device behavior from the host software. This simplifies zone allocation, but exposes a small number of active zones available for allocation to applications (e.g., 14 zones [50]). As a result, large-zone SSDs are more suitable for single or small numbers of tenant scenarios where the number of active zones required is not high. In addition, the application-agnostic fixed striping configuration does not adapt to workload profiles, resulting in low bandwidth utilization. Small-zone ZNS SSDs operate under similar hardware constraints but expose finer-grained, physical zones. Each zone is contained within a single die but sufficiently large to encompass at least one erasure block. Small-zone SSDs provide greater flexibility and much more active resources (e.g., 256 zones in our testbed ZNS SSD) to support more I/O streams. In addition to increased flexibility, small-zone SSDs reduce the need for application-level garbage collection, especially while managing large numbers of small objects. Recent studies also corroborate some of these points. Specifically, Bae et al. [3] advocate a zone to be as small as possible to reduce the interference caused by high zone-reclaiming latencies. ZNS+ [16] also prefers

Figure 2: The number of zone with actual write activity when running the *fill-random* workload over the RocksDB. The storage backend is ZenFS. The maximum number of active zones is 16 (red line).

small zones as it minimizes the latency of COPY operations performed frequently in its F2FS implementation.

### 2.4 The Problem: Lack of an Elastic Interface

The ZNS SSD brings in two key benefits. First, it exposes controllable garbage collection to host applications, eliminating obtrusive I/O behaviors precipitated by device internal bookkeeping I/Os. This also alleviates write amplification and reduces flash over-provisioning. Second, it only allows sequential writes within a zone and thereby mitigates certain I/O interference observed in a conventional SSD. Both prior studies [3, 8, 16, 45] and our characterizations (§3) below demonstrate these points. However, existing ZNS SSDs have one significant drawback: **the zoned interface is static and inflexible**. After a zone is allocated and initialized, its maximum performance is fixed regardless of the underlying device capability, its I/O configurations cannot adapt to runtime workload characteristics, and cross-zone I/O interference yields unpredictable I/O executions.

First, the performance profile of a zone-sized storage partition hinges on physical zone placement and stripe configuration, which should align with application requirements. Despite significant benefits from the flexibility of the user-defined logical zone, application-managed zone configuration would sustain sub-optimal performance due to the lack of knowledge of other tenants sharing the device. In addition, it imposes another burden on application developers, as with OC SSDs.

Second, it is non-trivial to develop a complete application profile that captures every aspect of I/O execution characteristics, such as read/write block size and distribution, I/O concurrency, and command interleaving degree. The existing zoned interface fails to adapt to the changing workload behavior. Users have to over-provision the zone resources when configuring a zone based on the worst-case estimation.

In Figure 2, it is shown that the RocksDB over ZenFS [7] actively writes to only a fraction of the zones it maintains in the *active* state. This leads to inefficient utilization of valuable active resources in the ZNS SSD. Similarly, file systems like BtrFS [36] and F2FS [25] support ZNS SSDs but write user data to only one zone at a time, resulting in suboptimal utilization of the available active resources. This issue is fur-

ther exacerbated when the device has multiple namespaces serving different applications. In such cases, each application only utilizes a fraction of the available bandwidth, wasting valuable active resources in the ZNS SSD.

Third, a zone is not a completely performance-isolated domain, and co-located zones interact with each other in a non-deterministic fashion. Ideally, each tenant should receive a weighted share based on the consolidation degree. Specifically, its housing application should achieve its targeted performance when the SSD is under-utilized but receive a proportional degradation when the SSD is over-subscribed. However, unlike its predecessor OC SSD, ZNS SSDs manage zone allocation and wear-leveling internally with no strong isolation support and expose an opaque view to applications, yielding unpredictable performance interference and I/O execution unfairness. Such an issue could be mitigated in a conventional SSD where FTL and GC blend and distribute blocks across channels and dies uniformly regardless of the original command flow, ensuring the attainment of the maximum bandwidth and equal utilization of channel and die.

### 3 Performance Characterization of a ZNS SSD

This section characterizes a ZNS SSD with a focus on understanding why existing ZNS interfaces are static and inflexible. We then discuss the possibilities of addressing the problem.

#### 3.1 Experimental Setup

Device HW Parameters	Specification
Capacity	3,816 GB
Channels #	16 Channels
NAND Dies #	128 Dies
NAND Page Size	16 KB
NAND Channel B/W	~600 MB/s
Physical Zone Size	96 MB
Read B/W per Physical Zone	~200 MB/s
Write B/W per Physical Zone	~40 MB/s
Maximum Active Zones #	256

Table 1: The commodity ZNS SSD specification.

**ZNS SSD and testbed.** We use a commodity ZNS SSD for characterization. Table 1 presents its hardware details. It has 40,704 physical zones where each 96MB-size zone consists of NAND erase blocks solely on a single die, and supports a maximum of 256 open zones simultaneously. We then configure various logical zones using such fine-granular units. We also prepare a conventional SSD with an equivalent architecture for a fair comparison. Our server has two 2.50GHz E5-2680v3 Xeon processors with 256GB DDR4 DRAM, and both SSDs are connected to  $\times 4$  PCIe Gen3 slots directly.

**Workloads and performance metrics.** We use the Fio benchmark tool [15] running on the SPDK framework [43] to generate synthetic workloads. We report both per-IO average/tail latency as well as achieved bandwidth. We add a thin layer to the SPDK to implement the logical zone concept and realize different zone configurations. Given the ZNS protocol, we regulate the write workloads to sequential accesses on a

Figure 3: System model, SW stack, and I/O path of a multi-tenant ZNS SSD deployment. RD/WR=Read/Write. The write cache flushes data to the NAND flash asynchronously. Zone resets are completed after invalidating the mapping layer, where NAND blocks are erased lazily.

single logical zone in the following experiments, where read workloads are issuing random I/Os unless specified.

#### 3.2 System Model

We consider a typical system setup with a five-layered view to facilitate the understanding of a multi-tenant ZNS SSD deployment and dissect the I/O behavior (Figure 3-a). From the top-down perspective, the first layer contains a few co-located tenants, each running a storage application (e.g., blob store, F2FS, and RocksDB). Next, a tenant exclusively owns one or several namespaces based on the required capacity. A namespace provides independently configurable logical zones (layer 3), exposing a private logical block address space. By manipulating the logical zone setup, a namespace can be configured differently to meet the capacity and parallelism requirements. Within a logical zone, reads happen everywhere, while writes are only issued in an append-only manner. This is unique to a ZNS SSD and in significant contrast to a conventional SSD, which can be viewed as a fixed or statically configured SSD.

A logical zone comprises several physical zones (fourth layer). The number of physical zones per logical zone is typically fixed within a namespace. The logical-to-physical zone mapping can be arbitrary regardless of the request serving order and device occupancy. However, the logical zone must not share its physical zones with each other to conform with the ZNS protocol. At the bottom layer, a physical zone is placed on one channel/die following the device specification. The zoned block device (ZBD) layer (Figure 3-b) is the central component across the storage stack that abstracts away architectural details of a ZNS SSD. It provides three functionalities: (1) interacting with the application on namespace/logical zone management; (2) orchestrating the logical-to-physical zone mapping in consideration of the application requirement; (3) scheduling a sequence of I/O commands to maximize device utilization and avoid head-of-line blocking. Figure 3-c shows the IO path of read/write/reset requests. We carefully configure each layer when designing characterization experiments.

#### 3.3 Zone Striping

Since a logical zone is usually configured as an array of physical zones spatially, similar to RAID 0, one could apply the

Figure 4: Read bandwidth varying the stripe size for different types of zones.

Figure 5: Read/Write bandwidth varying the number of physical zones.

Figure 6: Read bandwidth under three channel overlapping (OL) allocations.

Stripe Size	Avg. Lat(us)	P99.9 Lat. (us)	B/W (MB/s)
4KB	64	76	59
8KB	71	84	108
16KB	88	103	175
32KB	163	269	190
64KB	314	619	198

Table 2: Read I/O average/P99.9 latency and bandwidth varying the stripe size on a physical zone.

striping technique to achieve higher throughput, especially for large-sized I/Os. Zone striping segments data blocks across multiple physical zones and access them concurrently. There are two configuration parameters: (1) *Stripe size* is the smallest data placement unit in a stripe, and (2) *Stripe width* defines the number of physical zones in an active state and controls the write bandwidth.

### 3.3.1 Basic Performance

When there are enough outstanding I/Os submitted to an SSD, unsurprisingly, the optimal striping efficiency is achieved when the stripe size matches the NAND operation unit (i.e., NAND page size). As shown in Table 2, the achieved per-die bandwidth increases slowly after the 16KB stripe size. In terms of latency, the access time reduction is non-linear for sizes smaller than a NAND page (16KB). When the I/O size is larger than 16KB, the average latency rises proportionally to the I/O unit because each request has to access the die multiple times sequentially. Next, we change the logical zone setup and see the efficiency of different stripe sizes. We use  $N$ -zones to refer to a logical zone configuration, where  $N$  is the number of physical zones in a striping. As shown in Figure 4, when issuing 2MB reads (which generates enough I/O to construct a full stripe I/O on each physical zone), for different zone configurations, the bandwidth over various stripe sizes shows a similar result with the single-die performance. On the other hand, a wider width that fully uses the stripe size ( $stripe\_size \times stripe\_width$ ) achieves higher bandwidth. For example, the 4KB stripe size in 8-zones achieves 37.3% higher read bandwidth than the 8KB stripe size in 4-zones. Note that the stripe size does not significantly affect the write performance as one can coalesce stripes on the same physical zone into a single device I/O and submit it at once. Instead, the stripe width determines the maximum write bandwidth.

### 3.3.2 Challenge #1: Application-agnostic Striping

When deciding the optimal stripe size and width, one should consider the application I/O profile dynamically, including

request type, size distribution, I/O size efficiency, and concurrency. However, the existing zoned interface lacks such support and hinges on users' domain knowledge during configuration. A large stripe may hurt performance if the size of sequential user I/O is smaller than the size of a full stripe. On the other hand, too small a stripe also hurts the I/O efficiency of the device; a 4KB stripe with an 8-zone or wider width significantly lags behind 8KB or larger stripes in Figure 4. A wide stripe width sustains high performance per logical zone. However, since the device has a limited amount of active resources, it will instead limit the maximum number of active logical zones and jeopardize application concurrency.

**Observation:** The use of logical zones with striping is beneficial for the application, but zone striping should be an adaptive configuration determined based on the total amount of active zones and application profiles. A ZNS SSD has to provide enough active logical zones to not only cope with application concurrency but also max out the device bandwidth by adjusting the stripe width dynamically. An ideal strip size can be the NAND page size, but it also has to be adjusted to the stripe width to provide a consistent full stripe size.

## 3.4 Zone Allocation and Placement

A ZNS SSD allocates physical zones across dies/channels, mainly taking access parallelism and wear-leveling into consideration. Upon an allocation request, the ZNS SSD traverses the die array following a certain order, and then selects the next available die to place each physical zone. Within a determined die, it chooses blocks with the least P/E cycles based on opaque wear-leveling policies.

### 3.4.1 Basic Performance

Zone allocation should be locality-aware and parallelism-aware. A larger-sized logical zone is expected to observe higher read/write bandwidth because it spreads physical zones across *different* channels and dies in a deterministic sequence and achieves more I/O parallelism. The maximum performance is obtained when I/Os access all channels and dies without blocking. We configure the stripe size to 16KB and increase the number of physical zones in a logical zone ( $N$ ), then measure the I/O bandwidth of a single logical zone under four I/O profiles (Figure 5). The performance of 2MB reads with queue depths 1 and 2 (i.e., 2MB-RD-QD1/2MB-RD-QD2) keeps increasing until the number of physical zones approaches 20. But they max out for different reasons. The

Figure 7: Bandwidth and tail latency varying with the die overlapping ratio.

Figure 8: Read tail latency varying the write bandwidth (ZNS vs Conventional SSD)

Figure 9: Bandwidth under RD-RD and WR-WR congestion due to the die-collision.

QD2 case is bounded by the PCIe bandwidth (i.e., four Gen3 lanes or 3.2GB/s), whilst the QD1 scenario is simply limited by the application as it cannot issue enough outstanding I/Os at that queue depth. In terms of 4KB random read with 32 queue depth and 2MB sequential write, they sustain 80MB/s read and 40MB/s program bandwidth per physical die, respectively, requiring much more physical zones ( $\sim 40$  and  $80$ ) to utilize the channel or PCIe bandwidth fully.

### 3.4.2 Challenge #2: Device-agnostic Placement

An ideal allocation process should expose all of the internal I/O parallelism of a ZNS SSD to a tenant. However, the existing mechanism is opaque to housed tenants, where the global allocation pointer picks the next available die without considering the application’s prior allocation history or how it interacts with other tenants. This causes unbalanced zone placement, hurts I/O parallelism, and jeopardizes performance. We find two types of inefficient placements:

- **Channel-overlapped placement:** Concurrent zone allocations might cause overlapped zone placements across channels, limiting the maximum channel parallelism. Similarly, synchronized allocation requests might prevent placement alignment, again limiting the aggregated bandwidth. Figure 6 presents 4KB and 128KB random read bandwidth when increasing the QD for three inferior placements, where 2/4/8 physical zones contend for the same channel in a 16-zone configuration. Physical zones stay across 16 different dies that limit the maximum bandwidth. The 2-overlapped allocation outperforms the other two (i.e., 4-overlapped/8-overlapped) by  $1.7\times/2.9\times$  and  $1.7\times/2.5\times$  for 4KB and 128KB cases, respectively.
- **Die-overlapped placement:** An intra-namespace die overlapped placement limits the bandwidth and can be even more detrimental because a die can only process one operation at a time. We configure such an experiment by placing physical zones in the same die and gradually increasing the overlapping ratio. Figure 7 reports the logical zone’s sustained bandwidth and tail latency under two I/O profiles. When no physical zones share the same die, it achieves 1,128MB/s and 2,051MB/s along with 317us and 284us p99.9 tail latency for the 4KB random read and 128KB sequential read cases, respectively. With full overlap, we observe 47.2%/23.8% bandwidth drop and 87.1%/28.0% tail latency increase. Such performance degradation hap-

pens even when the overlapping ratio is lower than 25%, because both types of I/Os suffer from the head-of-line blocking issue at the overlapped dies.

**Observation:** It is challenging to infer the zone’s physical location without knowing the device’s internal specification. One may run a profiling tool in the runtime to extract the relation among different zones [3]. However, it does not eliminate the imprinted overlap at the allocation time. To maximize the I/O parallelism, one could build a device abstraction layer that (1) relies on a general allocation model of the device; (2) maintains a shadow view of the underlying physical device; (3) profiles its placement balanced level across different physical channels and dies.

## 3.5 I/O Execution under ZNS SSDs

A ZNS SSD eradicates background GC I/Os, thereby removing one form of performance non-determinism. Within a logical zone, writes happen sequentially, but reads are issued arbitrarily. When reads are congested, one would observe latency spikes under die/channel contention. If considering cross-zone cases, either *intra* or *inter* namespace, interference would be more severe than a conventional SSD because ZNS SSDs impose no physical resource partitions, and per die/channel bandwidth is narrow.

### 3.5.1 Basic Performance

Irrespective of the NAND block layout of a logical zone, its I/O access latency highly correlates with achieved bandwidth because there are no device internal I/Os that consume bandwidth and are hidden from user applications. To demonstrate this, we prepare a conventional SSD having the same hardware as the ZNS SSD and compare two SSDs under the mixed read-write scenario. We configure a logical zone for the ZNS SSD that spreads across all the channels and dies (i.e., 128-zone configuration with 16KB stripe size) to match the conventional one. The fragmented conventional SSD is 70% filled and preconditioned with 128KB random writes. Then we run 8 read threads—where each issues one 128KB read I/O to all the dies uniformly random—and 1 write thread that performs sequential write at a fixed rate. Figure 8 reports the read/write tail latency as we increase the write bandwidth. More writes on a ZNS SSD leave less bandwidth headroom for reads and cause the latency to increase. However, for the fragmented conventional SSD, the internal GC activities make even less bandwidth available to serve reads

due to write amplification. For example, when the write bandwidth is 1,000MB/s, the p99.9 read and write latency of the conventional SSD is  $4.3\times$  and  $2.8\times$  worse than the ZNS one. In terms of the read throughput, the conventional SSD shows  $1.1\times$  and  $1.6\times$  lower throughput than the ZNS SSD at the 200MB/s and 1,000MB/s write bandwidth, respectively.

### 3.5.2 Challenge #3: Tenant-agnostic Scheduling

Existing zoned interfaces of ZNS SSDs provide little performance isolation and fairness guarantees for the inter-zone case, regardless of deployed workloads. One cannot overlook the read interference on a die because (1) an arbitrary number of zones can collide on a die, (2) the bandwidth of a single die is poor, and hence the interference becomes severe even under a very low load on the device, and (3) it causes a severe head of line blocking problem and degrades the performance of the logical zone. Since there is no internal GC in the ZNS SSD, The I/O determinism [26] proposed for the conventional SSD does not apply as well. Similar to conventional SSDs, the write cache, shared among all NAND dies, is an indispensable component of the ZNS SSD, buffering incoming writes and flushing to the NAND dies in a batch. Host applications will observe prompt write I/O completions when they are absorbed by the cache but experience considerable latency spikes when the cache overflows. This has not been an intractable issue in conventional SSDs because the device firmware blends all incoming write I/Os and constructs a single large flow spanning entire NAND dies, maintaining the cache eviction rate to the maximum device bandwidth. However, in the ZNS SSD, a write I/O must be flushed out to the designated NAND die with an inadequate program bandwidth, even with zone striping. In this situation, a heavy writer exhausts the available cache capacity and severely disturbs other short flows.

We set up two readers performing 128KB read I/O in different profiles: (1) queue depth 8 with 2-zones configuration, and (2) queue depth 2 with 8-zones configuration. Figure 9 shows the interference between two readers in a die-collision. The QD-8 reader easily obtains 97.2% of the total bandwidth of collision dies. Note that the interference and unfair bandwidth share also occurs in the conventional one, but only when the device bandwidth is fully saturated [23, 41]. We also demonstrate the write cache congestion in Figure 9. We first populate 15 logical zones with a stripe width of 8, and each physical zone is allocated to a dedicated die. The cumulative write bandwidth of 15 zones maxes out the PCIe bandwidth (3.2GB/s), and a single zone performs at  $\sim 213.3\text{MB/s}$ . In this case, a physical zone in the logical zone receives write at a lower rate than the maximum bandwidth ( $\sim 26.7\text{MB/s}$ ), and the write cache does not overflow. Then, we add one more writer with a narrow width of 2, which also runs on dedicated dies. Write I/Os towards the narrow zone are equally fetched by the device, but it soon consumes all available cache because of the scarce bandwidth ( $\sim 85\text{MB/s}$ ) of underlying physical zones. It degrades others' bandwidth by 27.3% or

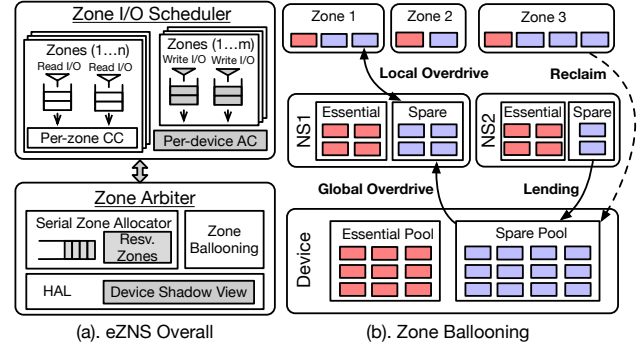

Figure 10: eZNS System Architecture.

155MB/s, and the device even fails to max out the PCIe bandwidth ( $\sim 2.4\text{GB/s}$ ).

**Observation:** When using ZNS SSDs in a multi-tenant scenario, one should first understand how different namespaces and logical zones share the channels and NAND dies of the underlying device, classify their relationships into competing and cooperative types, and employ a congestion avoidance scheme for the inter-zone scenario to achieve a fairness. Since there are no device bookkeeping operations, I/O latencies represent the congestion level on colliding dies. In addition, write cache congestion needs to be addressed globally. Thus, a possible solution is to design (1) a global central arbiter that decides the bandwidth share among all active zones; (2) a per-zone I/O scheduler that orchestrates the read I/O submission based on the congestion level.

## 4 eZNS: Enabling an Adaptive Zoned NS

This section describes the design and implementation of eZNS that realizes a new and elastic zoned interface. We use the gathered insights from our characterization experiments and address the aforementioned issues.

### 4.1 eZNS Overview

eZNS stays atop the NVMe driver and provides raw block accesses. eZNS exposes the *v-zone* interface that offers runtime hardware adaptiveness, application elasticity, and tenant awareness. We carefully design eZNS and spread its functionalities across the control plane and data plane. As shown in Figure 10, it mainly consists of two components. The first is the zone arbiter that (1) maintains the device shadow view in a hardware abstraction layer (HAL) and provides the basis for other components, (2) performs serialized zone allocation avoiding overlapped placement, and (3) dynamically scales the zone hardware resources and I/O configurations via a harvesting mechanism. The second is a tenant-cognizant I/O scheduler, orchestrating read requests using a delay-based congestion control mechanism and regulating writes through a token-based admission control. In sum, eZNS addresses the three issues discussed in §3.

## 4.2 Hardware Contract and HAL

We develop eZNS based on the following hardware contract, which are met by recent ZNS SSDs with small zones: (1) a physical zone consists of one or more erasure blocks on a single die; (2) the maximum number of active physical zones is a multiple of the number of dies, and all dies hold the same number of active zones when they are fully populated (i.e., the ZNS SSD evenly distributes physical zones over dies); (3) the zone allocation mechanism follows the wear-leveling requirements, indicating that consecutive allocated zones will not overlap on a physical die until all the dies have been traversed. We need to caveat that the last contract may not always be followed in allocations if the device firmware enforces a specific policy other than round-robin across dies. However, considering the large number of chips and the wear-leveling constraint, such cases are rare. Our mechanism doesn't require being cognizant of the two-dimensional geometric physical view of SSD NAND dies and channels or maintaining an exact zone-die mapping.

eZNS maintains a shadow device view, exposing the approximate data locality for zone allocation and I/O scheduling. Our mechanism (or HAL layer) only hinges on three hardware parameters from device specifications. The first one is the *maximum number of active zones* (or MAR, maximum active resources). This is based on an observation that the MAR is generally in proportion to or a multiple of the number of physical dies on the SSD. One could estimate the number of active zones that a die could hold by deliberately controlling the zone allocation order in an offline calibration experiment (§3.4). The second parameter required is the *NAND page size* used for striping configuration. For example, 16KB is a de facto standard for most TLC NVMe drives and is well-known for system developers. The SSD shows the best efficiency when the stripe size is aligned with it (§3.3), and thereby, we choose the stripe size as a multiple or factor of the NAND page size that is closest to avoid inefficient stripe reads for sequential workloads. These two parameters reflect the device's capabilities. The third one is the *physical zone size*, deciding how a logical zone and strip groups are constructed. With such information, HAL provides a shadow view having a consistent MAR (e.g., 16) and the size of a zone (e.g., 2GB) regardless of the underlying device.

## 4.3 Serial Zone Allocator

eZNS develops a simple zone allocator that provides three guarantees: (1) it ensures that each stripe group comprises a list of consecutive and serial opened physical zones, following the firmware-enforced internal order; (2) there is no die collision within a stripe group; (3) across stripe groups, die collision could happen for writes only if available active physical zones are fully populated across all the dies. Given the above device model, the number of stripe groups colliding on a die is  $\frac{\text{Maximum \# of active zones}}{\text{Die \#}}$  at most. Channel collision would not be an issue because its bandwidth is usually higher

Figure 11: Example of eZNS *v-zone* structure.

than the aggregated program bandwidth across dies.

Our allocator works as follows. It has a per-device request queue, buffering OPEN commands (including implicit ones followed by writes) from all logical zones. Our allocator serves each logical zone request atomically. Since the completion of a zone OPEN command does not guarantee that the zone is actually allocated on a physical die, we implement a zone reservation mechanism during zone opens—flushing one data block that enforces binding a die to the zone. Writes complete immediately as the write cache of the device absorbs a single block even in high load. To expedite this process, we proactively maintain a certain amount of reserved zones in serial order and provision them to an upcoming stripe group. Upon completion of the allocation, we then update the allocation history and write it into a reserved persistent region (metadata block) following the block for reservation. Hence, we preclude interleaved allocations from concurrently opened logical zones to prevent channel-overlapped placement and facilitate allocation reordering to mitigate die overlaps (§3.4.2).

## 4.4 Zone Ballooning

*v-zone*, a specialized logical zone, can automatically scale its I/O striping configuration and hardware resources to match changing application requirements in a lightweight fashion. Figure 11 illustrates an example of a *v-zone* structure. Similar to a static logical zone, a *v-zone* contains a fixed number of physical zones. However, unlike a static logical zone, it divides physical zones into one or more stripe groups. When *v-zone* is first opened or reaches the end of a previous stripe group, it allocates a new stripe group. All physical zones in the previous stripe group must be finished when the write pointer reaches the end of the stripe group, allowing an active *v-zone* to take active resources for only one stripe group. The number of physical zones in a stripe group is determined at the time of allocation according to the *local overdrive* mechanism, which enables flexible zone striping. To comply with the standard zone interface, *v-zone* has a size that is a power of 2, and its capacity is the sum of user-available bytes in physical zones.

Similar to the virtualization memory ballooning technique [5, 39, 47], zone ballooning allows a *v-zone* to (1) expand its stripe width by leasing spares from others when other namespaces are under low active resource usage; (2) return them when it finishes the stripe group either by writing to the end of the stripe group or explicitly issuing FINISH/RESET commands from the application.

#### 4.4.1 Initial Resource Provisioning

eZNS divides all the available and opened physical zones on the ZNS SSD into two groups: *essential* and *spare*. The *essential* group contains a minimal number of active physical zones that can max out the SSD write bandwidth ( $N_{essential}$ ), whilst the rest belong to the *spare* group ( $N_{spare}$ ). Our initial resource allocation follows the equal bandwidth partition principle. We choose the write I/O bandwidth as the minimum guarantee because writing resources (or active physical zones) of a ZNS SSD are scarce. Assuming the number of namespaces that a ZNS SSD holds is  $N_{ns}$  and the maximum number of active  $v$ -zones per namespace is  $MAR_{logical}$ . A namespace takes  $\frac{N_{essential}}{N_{ns}}$  exclusive active physical zones; when a  $v$ -zone in the namespace opens a new stripe group, it receives  $\frac{N_{essential}}{N_{ns} \times MAR_{logical}}$  assured essential ones which is also the minimum stripe width. In terms of *spare* zones, similarly, eZNS equally distributes them to a namespace ( $\frac{N_{spare}}{N_{ns}}$ ) during initialization. Both a  $v$ -zone and a namespace will expand/shrink their capacity to adapt to workload demands.

#### 4.4.2 Local Overdrive: Zone Expanding

eZNS provisions available spares from the *spare* group of its namespace to boost its write I/O capability. We realize this via an internal *local overdrive* operation while opening a new stripe group. The mechanism works as follows. First, it estimates the resource usage of the namespace by analyzing its previously opened  $v$ -zones, quantified as the exponentially weighted moving average over the number of active  $v$ -zones ( $N_{ActiveZoneHistory}$ ). Second, it checks the remaining spares from the spare group ( $N_{RemainingSpare}$ ) and reaps additional spares based on  $\frac{N_{TotalSpare}}{N_{ActiveZoneHistory}}$ . Essentially, a  $v$ -zone will receive more (fewer) spares if it embodies writing activities but the namespace only opens fewer (more)  $v$ -zones. Third, the  $v$ -zone conflates the harvested spares with assured essential ones for it to open the new stripe group, and the stripe width is rounded down to the nearest power of two for efficient resource management. Note that the *local overdrive* operates in a serial and best-effort fashion. Lastly, eZNS sets the baseline stripe size to 32KB at the minimum width for the optimal I/O efficiency of the device. It then reduces the stripe size for an overdriven zone according to the stripe width, down to the minimum block size of the device. For example, if the width gets two times wider, the stripe size is reduced by half. We determine the range of stripe sizes to optimize the performance as aforementioned in §3.3. The reduced stripe size further contributes to the I/O scheduler ensuring fairness (§4.5).

#### 4.4.3 Global Overdrive: Namespace Expanding

Across the whole device, our zone ballooning mechanism further reallocates spares across namespaces based on their latest write activity. We realize this via another internal *global overdrive* operation—lend spares from the spare group to each other. Unlike *local overdrive*, global overdrive is triggered

based on the write intensity across the entire drive. Specifically, our arbiter monitors the past  $N_{essential}$  opened physical zones across all active namespaces, computes their zone utilization, and redistributes the remaining spares from inactive namespaces to active ones. In the current design, we determine an *inactive* namespace as a namespace that has no allocation history in the last  $N_{essential}$  physical zone allocations of the device, and lent spares are equally distributed across active namespaces. When an *inactive* namespace becomes active again, eZNS marks the leased spares as recall spares and leased namespaces release them to the global pool as soon as they FINISH/RESET the stripe group in  $v$ -zones. eZNS then returns them to the original namespace at the next *global overdrive* operation.

#### 4.4.4 Reclaim: Zone/Namespace Compaction

Generally, an overdriven  $v$ -zone after entering the FINISH state will return spare zones. Therefore, spare zones circulate as long as namespaces continue to write to  $v$ -zones. However, when a namespace overdrives  $v$ -zones, which becomes *inactive* without releasing them, the arbiter has to use a *reclaim* operation to take back the spares to prevent resource leakage. To ensure no slowdown on the performance path, we employ an asynchronous window-based monitoring scheme, where the arbiter bookkeeps the status of each *inactive* namespace and continuously counts how long its status is in the read-only state. If a namespace presents no write I/Os for a certain amount of time,  $T_{ReadOnly}$ , the arbiter triggers the reclaim procedure to proactively collect the spare zones. The execution cost of *reclaim* depends on the configuration within the opened stripe group. If there are committed writes on the zone, *reclaim* will trigger a zone compaction and perform a sequence of I/O reads/writes, i.e., finishing existing zones, opening a new stripe group with shrunk width, and copying data to the new one. Once the migration is done, the spare zones can be returned to the global spare pool.

The zone reclaiming indeed brings GC-like overheads back to the system. Thus, it is crucial that the system does not trigger the operation in normal conditions. In eZNS, zone reclaiming is only performed when namespaces have no write activity for two cycles of global overdrive. This is likely to happen infrequently, such as when an application undergoes a significant change in its running state. Moreover, reclaiming is triggered in a lazy fashion, executed in the background, and regulated by the scheduler to limit its performance impact. As a result, eZNS can avoid triggering zone reclaiming in normal conditions, maintaining high performance and efficiency.

### 4.5 Zone I/O Scheduler

eZNS mindfully orchestrates I/O reads/writes with the goal of providing equal read/write bandwidth shares among contending  $v$ -zones, maximizing the overall device utilization, and mitigating superfluous head-of-line blocking when different types of requests interleave. Our zone I/O scheduler com-

prises two components: congestion-avoiding read scheduler and cache-aware write admission control.

#### 4.5.1 Congestion-avoid Read Scheduler

Our design is based on the observations that (1) ZNS SSDs have no internal housekeeping operations; (2) write I/Os are sequential and synchronous. Hence, the read latency is stable and low until the die becomes congested, and it is thus possible to detect congestion directly via latency measurements.

eZNS introduces a hierarchical design that performs weighted round-robin scheduling firstly across active namespaces and then delay-based congestion control across each intra-namespace *v-zones*. By conforming to the NVMe architecture, we create per-namespace NVMe queue pairs and offload the round-robin scheduling to the device. Then, we employ a Swift-like [24] congestion control mechanism to decide the bandwidth allocation for each stripe group in the *v-zone*, where the delay is the device I/O command execution latency. As shown in Algorithm 1, during the congestion-free phase, upon a read I/O completion, we additively increase (AI) the congestion window until it approaches the maximum size (line 6). Since the congestion window (*cwnd*) is shared in the stripe group, when set to the stripe width, it indicates that there is one outstanding I/O per die in the sequential case. The SSD can max out its per-die bandwidth with a few outstanding I/Os. Thus, when the *cwnd* starts with the stripe width, it quickly ramps up to the device bandwidth capacity. Further, we limit the maximum congestion window (*cwnd*) to  $4 \times \text{stripe\_width}$  to minimize the software overheads when handling excess concurrent I/Os and avoid a meaningless rapid growth of *cwnd* that would imperil the efficiency of the MD phase. When congestion happens, we reduce the congestion window multiplicatively (line 4), whose ratio depends on the latency degradation degree. All the physical zones within a stripe group share the same congestion status. It is reasonable because sequential read bandwidth will be capped by the most congested physical zone. Random reads usually will not trigger frequent *cwnd* decrements because the minimum window size is large enough to absorb them. Our congestion control works cooperatively with the reduced stripe size of the overdrive and ensures a fair share of bandwidth regardless of the width of the stripe group.

#### 4.5.2 Cache-aware Write Admission Control

Due to the non-linear write latency and the shared architecture, it is inappropriate to implement a local mechanism to mitigate the problem. Unlike the read congestion case, write congestion happens globally across all zones from all namespaces (§3.5). Therefore, eZNS monitors the global write latency and regulates writes using a token-based admission control scheme. We generate tokens periodically (ALG 1 lines 14–16) and admit write I/Os in a batch for each active *v-zone* to ensure overflow rarely happens. This requires a latency monitor to analyze the write cache eviction activity (ALG 1 lines 8–12). Here, we profile the block admission rate (defined as

---

#### Algorithm 1 Zone I/O Scheduler

---

```

1: procedure READ COMPLETION()
2:   lat_thresh  $\leftarrow$  500us
3:   if io_lat > lat_thresh then
4:     cwnd = max(1, cwnd  $\times$   $\frac{\text{lat\_thresh}}{2 \times \text{io\_lat}}$ )
5:   else  $\triangleright \alpha$  = additive factor
6:     cwnd = min(stripe_width  $\times$  4, cwnd +  $\alpha \times \frac{\text{io\_count}}{\text{cwnd}}$ )
7: procedure WRITE LATENCY MONITOR()
8:   On t every 10ms
9:     total_lat =  $\sum_{\text{active\_zone}} \text{per\_block\_lat}$ 
10:    total_ios =  $\sum_{\text{active\_zone}} \text{num\_ios}$ 
11:    avg_lat(t) =  $\frac{\text{total\_lat}}{\text{total\_ios}}$ 
12:    block_admission_rate =  $\frac{\text{avg\_lat}(t-1) + \text{avg\_lat}(t)}{2}$ 
13: procedure WRITE TOKEN GENERATOR()
14:   On every 1ms
15:   for pending write zones do
16:     token +=  $\frac{\text{now} - \text{last\_refill}}{\text{block\_admission\_rate}} \times \text{stripe\_width}$ 

```

---

the minimum delay between two consecutive write blocks) and adjust the token generation rate based on its normalized average latency. This is based on an empirical observation that the latency of the write projects its capacity share in the write cache. Hence, we equalize the latency for all write zones and calculate available tokens using the average value. Additionally, we update the available tokens based on the elapsed time from the last token refill upon a write submission. By doing so, we expect writes are self-clocked in the congestion-less condition.

Note that (1) when read and write I/Os mix on a physical die, the total aggregate bandwidth will drop due to the NAND interference effect. However, our read scheduler and write admission control require little coordination because both modules only use the latency (gradient) as a signal to infer the current bandwidth capacity; (2) we coalesce stripes for the same physical zone within a user I/O and submit one write I/O to the device in a batch, and thus, a small stripe size does not degrade the write bandwidth.

## 5 Evaluation

We add a thin layer in the SPDK framework [43] to implement eZNS and realize the *v-zone* concept. The primary reason for choosing the SPDK approach was its ease of implementation and integration into the software stack of a storage server accessible by remote clients. Moreover, the SPDK-based design can also be used in a local system to serve virtual machines through the SPDK vhost extension. This approach allows the storage server to provide efficient and high-performance I/O operations, while remaining compatible with existing software stacks. We use the same test environment as in §3.1. Non-SPDK applications require a standard ZNS block device exposed via the kernel NVMe driver; thus, we set up eZNS as a disaggregated storage device over RDMA (NVMe-over-RDMA) and connect to it from the host using the kernel NVMe driver.

Figure 15: Efficiency of eZNS on handling read-read, write-write, and read-write congestion. (CC=Congestion Control, AC=Admission Control)

**Micro-benchmarks:** We use FIO [15] to generate synthetic workloads, and allocate a separate thread for each worker when the workload writes to multiple namespaces or zones. For read workloads, we first precondition the namespace by performing sequential writes for the entire range of read I/O. Additionally, we perform a pre-calibration step to determine the die allocations in case the evaluation requires a die-level collision.

**Ported Applications:** We use RocksDB as a real-world ZNS application, to evaluate the performance of eZNS. We run RocksDB over ZenFS [7] to enable the ZNS support. As eZNS complies with the standard NVMe ZNS specification, no modification is required for the application and ZenFS. We initialize the DB instance with 500M entities of 20-byte keys and 1,000-byte values.

**Default *v-zone* Configuration:** By default, eZNS creates four namespaces (NS1–4), each of which is allocated 32 essential and 32 spare resources. Since each namespace provides a maximum of 16 active zones, the minimum stripe width for *v-zone* is 2 with a stripe size of 32KB. However, eZNS can overdrive the width up to 16 with a stripe size of 4KB. For a fair comparison, we prepare a static logical zone configured with stripe width and size of 4 and 16KB, respectively; hence, it also accesses full device capability when the application populates enough active logical zones. Both a *v-zone* and a static logical zone comprise 16 physical zones. Different configurations are used for single-tenant evaluation (single namespace) as specified in Section 5.3.

## 5.1 Zone Ballooning

We demonstrate the efficiency of zone ballooning when handling large writes (i.e., 512KB I/O with a queue depth of one).

First, within a namespace, we compare the performance between a *v-zone* and a static logical zone, where the number of writers is configured to 4, 8, and 16, respectively. Each writer submits a write I/O to different zones. Our *local overdrive* operation can reap more spare zones and lead to better throughput. As shown in Figure 12, the *v-zone* outperforms the static one by  $2.0\times$  under the 4-writer case as 4 static logical zones enable only 16 physical zones while 4 *v-zone* overdrive the width to 8 and expand to 32 physical zones. In the 8-writer and 16-writer cases, *v-zone* reduces the overdrive width accordingly and utilizes the same number of physical zones (32 and 64, respectively) with the static logical zone.

To evaluate eZNS’s adaptiveness under dynamic workloads, we set up overdriven zones from different namespaces. The first three namespaces (NS1, NS2, and NS3) run two writers, while the fourth namespace (NS4) runs eight. NS1, NS2, and NS3 stop issuing writes at  $t=30s$  and resume the writing activity at  $t=80s$ . We measure the throughput and spare zone usage of four zones for a 100s profiling window (Figures 13 and 14). When the other three zones become idle, the *v-zone* from NS4 takes up to  $3\times$  more spare zones from other namespaces using the *global overdrive* primitive, and maxes out its write bandwidth ( $\sim 2.3GB/s$ ). It can then quickly release the harvest zones when other zones start issuing writes again.

## 5.2 Zone I/O Fairness

We evaluate our I/O scheduler in various synthetic congestion scenarios by placing competing zones in the same physical die group. We compare the performance of all co-located zones when enabling and disabling our mechanism. The zone ballooning mechanism is turned off for all cases. We report per-thread bandwidth in Figure 15.

Figure 16: *readwhilewriting* workload on a single tenant configurations. Static has stripe width of 16. (S: 4KB stripe, L: 16KB stripe)

Figure 17: Latency of *db\_bench* workloads (2 overwrite, 2 randomread) on different namespaces over eZNS and static zone.

Figure 18: Throughput of *db\_bench* workloads (2 overwrite, 2 randomread) on different namespaces over eZNS and static zone.

**Read-Read Fairness.** We run a sequential read of 128KB I/O size at two types of zones on co-located dies. To equally load the physical dies, we populate more threads for lower-width zones. For example, a zone with a width of 2 runs four threads on each stripe group, while a zone with a width 8 has only one thread. As shown in Figure 15-a, in scenario 1, when disabling our congestion control mechanism, Zone A (configured with stripe width 2 and stripe size 32KB, QD-1) and Zone B (configured with stripe width 8 and stripe size 8KB, QD-32), even holding the same sized full stripe, achieve 76MB/s and 1287MB/s, respectively. This is because the zone with the higher QD dominates on the competing die. Our scheme effectively controls the per-zone window size and ensures that each zone submits the same amount of outstanding bytes. Hence, both Zone A and Zone B sustain 290MB/s. In scenarios 2 and 3, we change the Zone A stripe configuration to <stripe width 4, stripe size 16KB, QD-1> and <stripe width 8, stripe size 8KB, QD-1>, and observe similar behavior when turning off the read congestion logic. In scenario 3, the congestion level on the die gets lowered as Zone A only submits one 128KB I/O (which was 4 and 2 in scenarios 1 and 2, respectively). Hence the read latency also becomes below the threshold, and the I/O scheduler chooses to max out the bandwidth.

**Write-Write Fairness.** We carefully create different write congestion scenarios and see how our admission control operates. The workload used is a sequential write of 512KB size. In the first scenario, we co-locate 16 regular write zones (Zone A, where each has a striping width of 8 with 8KB stripe size and submits write I/Os at 5ms intervals, sustaining 95MB/s maximum throughput) with a busy writer (Zone B, that has width 2 and 32KB stripe size, submits I/O without interval delays, achieving 85MB/s at most). Figure 15-b reports the bandwidth utilization of one regular zone (Zone A) and the busy writer (Zone B). Our admission control mechanism limits the write issuing rate of Zone B and gives more room at the write cache to the regular zone (Zone A), leading to 35.7% bandwidth improvement per thread. Next, we set up a highly-congested case by changing 16 regular zones to busy writers (scenario 2). As described in §4.5.2, our scheme equally distributes the write bandwidth share across competing zones, and Zone B receives 56.8% of the total bandwidth of 2 physical zones. The last scenario is a collision-less one at the die

level where we eliminate the overlapping region among all the write zones by populating active physical zones lesser than the number of dies. Similarly, when enabling the admission control, the bandwidth allocated for Zone B slightly decreases ( $\sim 7.2\%$ ) to avoid cache congestion, and the overall device bandwidth is increased by 24.7%.

**Read-Write Fairness.** We examine how our congestion control mechanism coordinates with the admission control when handling read/write mixed workloads. In this experiment, we set up three types of zones: (1)  $\times 16$  regular readers (Zone A), where each has a striping width of 2 and 32KB stripe size, performing 128KB random read at queue depth 32, across all physical dies; (2) 1 busy writer (Zone B), whose striping width is 2 with 32KB stripe size; (3)  $\times 16$  regular writers (Zone C), which has a striping width of 8 and 32KB stripe size each, submitting I/Os under 5ms interval. Both B and C issue 512KB large writes. Figure 15-c reports their per-thread bandwidth. When disabling our scheduler, each reader achieves 199.6MB/s but writes are jeopardized significantly, where Zone B and Zone C can only achieve 19.3% and 27.3% of their maximum bandwidth. As we gradually turn on our mechanisms, the congestion control shrinks the window size such that more bandwidth is allocated to the writes. Further, the admission control then equally partitions bandwidth among competing writing zones. As shown in the CC+AC case, zone A, B, and C can sustain 71.6%, 57.5%, and 70.1% of their maximum bandwidth capacity, respectively.

### 5.3 Application: RocksDB

To evaluate eZNS in a real-world scenario, we use RocksDB [35] over the ZenFS storage backend. In addition to the built-in utility in the RocksDB *db\_bench* tool, we port YCSB workload generators [4] for the mixed workload evaluation.

**Single-tenant performance.** First, we evaluate the performance of a single tenant using the *readwhilewriting* profile of the *db\_bench*, which runs one writer and multiple readers. This workload profile demonstrates a read/write mixed scenario. In the case of a single-tenant configuration, eZNS creates a single namespace on the device and allocates 128 essential and 128 spare resources to it. Since only two stripe widths, 8 and 16, are possible in this configuration, eZNS sets the stripe size to 16KB for the width of 8 to avoid the namespace running only on large stripe sizes. We compare

Figure 19: Read latency of YCSB workloads (A/B/C/F) on different namespaces over eZNS and static zone.

Figure 20: Throughput of YCSB workloads (A/B/C/F) on different namespaces over eZNS and static zone.

Figure 21: Comparison of Avg. Read Latency for 4KB I/Os at various depths between the host-managed zone access and eZNS.

the performance of eZNS over two static configurations, both with a stripe width of 16, but with different stripe sizes of 4KB and 16KB. Since there is only one namespace on the device, eZNS always overdrives *v-zones* to the width of 16, which is identical to the static configurations. Therefore, both the static namespace and eZNS can exploit all available bandwidth on the device. However, the I/O scheduler of eZNS helps mitigate interferences between zones and improves overall application performance. Figure 16 shows that eZNS improves the P99.9 and P99.99 read latency by 28.7% and 11.3% over the static configurations with a stripe size of 16KB and 4KB, respectively. Additionally, eZNS also improves the throughput by 11.5% and 2.5% with a stripe size of 4KB and 16KB, respectively

**Multi-tenant Performance.** Next, we set up instances of *db\_bench* on four namespaces (A, B, C, and D), each with a different workload profile. A and B perform the *overwrite* profile, while C and D execute *randomread* concurrently. We run the benchmark for 1,800sec and report the latency and the throughput. Figure 17 shows that our I/O scheduler significantly reduces P99.9 and P99.99 read (C/D) latency by 71.1% and 20.5%, respectively. In terms of throughput, eZNS improves write (A/B) and read (C/D) throughput by 7.5% and 17.7%, respectively. Furthermore, while the read latency and throughput are improved, the write latency is either maintained at the same level or decreased compared to the static configuration because eZNS moves the spare bandwidth from read-only namespaces (C/D) to write-heavy ones (A/B).

**Mixed YCSB Workloads.** YCSB [14] is widely used to benchmark realistic workloads. In our experiments, we run YCSB workload profiles A, B, C, and F on each of the six namespaces. We exclude YCSB workload profiles D and E because they increase the number of entities in the DB instance during the benchmark. As YCSB-C (read-only) does not submit any write I/Os during the benchmark, eZNS triggers *global overdrive* and rebalances the bandwidth to the write-most namespaces (A and F). Figure 19 shows that the I/O scheduler improves the P99.9 read latency of read-intensive workloads (YCSB B and C) and also the read-modify-write one (YCSB F) by 79.1%, 80.3%, and 76.8%, respectively. The throughput improvement from global overdrive is up to 10.9% for the write-most workload A in Figure 20.

## 5.4 Overhead analysis

**End-to-end read latency overhead.** Since eZNS serves as an orchestration layer between the physical ZNS device and the NVMe-over-Fabrics target, there may be some overhead when the I/O load is very low. To measure this overhead, we conducted a quantitative analysis using 4KB random read I/Os and compared it with host-managed zone access, where the host directly accesses the physical device without eZNS. Figure 21 demonstrates that eZNS does not add a noticeable latency overhead for I/O depths up to 8. As the I/O depth goes over 16, up to 14.0% overhead is observed due to the I/O scheduler delaying the I/O submission. However, the scheduler provides significant advantages in real-world scenarios as shown in previous experiments.

**Memory footprint.** eZNS relies on in-memory data structures for managing *v-zone* metadata, including the logical-to-physical mapping and scheduling statistics. Additionally, it maintains a copy of the physical zone information to reduce unnecessary queries to the device, enabling faster zone allocation and deallocation. In our current implementation, the size of *v-zone* metadata is less than 1KB, and the size of physical zone information is smaller than 64 bytes. For our testbed SSD with four namespaces, each with 1TB of capacity, *v-zone* metadata and physical zone information require 2MB and 2.5MB of memory, respectively. Compared to the memory requirements of the page-mapping in conventional SSDs, the memory usage of eZNS is negligible.

## 6 Related Work

**Early ZNS Exploration.** Researchers have made initial efforts to understand the ZNS interface and integrate it into the host storage stack. Theano Stavrinou *et al.* [44] argue for a shift in research to the zone interface and discuss future directions (e.g., applying application-level information for zone management and I/O scheduling). Hojin Shin *et al.* [42] develop a performance analysis tool for a ZNS SSD and profile its parallelism, isolation, and predictability properties. Compared with our study, they didn't investigate the underlying device's internal mechanisms when realizing the zoned namespace interface and, thereby, are unable to correlate the observed performance with the ZNS SSD characteristics. ZNS+ [16] enhances the existing interface with two

new architectural primitives to optimize LFS file systems. With such support, the authors then propose copy-back-aware block allocation and hybrid segment recycling techniques. Hanyeoreum Bae *et al.* [3] prioritize I/O requests for less congested zones using an interference map, whilst updates incur significant overheads. Although revising the ZNS interface and exposing the physical allocation of zones could potentially eliminate this overhead, it may not be feasible for existing devices due to vendors’ resistance to disclosing internal architecture and policies. eZNS uses a delay to determine congestion and doesn’t require an allocation map. Furthermore, eZNS addresses such as read and write differences, zone striping, and bandwidth provisioning issues that were not discussed in their work. Minwoo Im *et al.* [18] improved ZenFS on small-zone SSDs by introducing read/write parallelism with a multi-threaded I/O engine and lifetime-based zone management at the application level. However, it requires adjusting the RocksDB parameters to match the device capability instead of the workload-optimized parameters. This can increase the complexity of parameter configuration, resulting in sub-optimal settings for the workload. eZNS maximizes parallelism within the thin layer, regardless of the underlying device and the application profile. It exploits the device’s parallel I/O processing capability that can be executed on a single thread.

**Addressing Inefficiencies of Conventional SSDs.** Early SSD researches [2, 11, 17, 31] focused on internal parallelism and tradeoffs between concurrency, locality, bandwidth, capacity, performance, and lifetime. Modern SSDs handle random write patterns with page mapping FTL, write-cache, and superblock concepts [49] that group blocks together. It benefits from high parallelism that transforms writes into sequential NAND programming. However, multi-tenancy workloads cause interference and high write amplification factor (WAF). ZNS SSDs eliminate garbage collection and fix WAF to one, but require careful parallelism management across zones to avoid degraded device utilization. In addition, future QLC-based ZNS SSDs may have fewer active zones due to a multi-pass programming algorithm [21]. eZNS addresses these challenges by adjusting the parallelism of each logical zone based on the number of namespace flows, providing fully dynamic parallelism and maximizing device capability while presenting an identical logical view to applications.

IODA [26] is an I/O deterministic flash array that uses the I/O determinism feature and exploits data redundancy for a strong latency predictability contract. SSDs can fail an I/O to allow predictable I/Os through proactive data reconstruction. We target the ZNS SSD, where there are no random I/Os, and GCs are user-controlled. This opens up a different design space. Although techniques addressing GC-related interference are not beneficial to GC-free ZNS SSDs, others such as Engurance Group(EG) and NVM Set can be useful to ensure physically-isolated zone allocation. eZNS can take advantage of the geometry hints via EG (or even finer-grained NVM

Sets). Unfortunately, there is no currently-available SSD that supports both ZNS and EG, but it will be an interesting direction for future work.

**Open-Channel SSDs.** These drives have no mapping layer in the controller and directly expose a set of physically contiguous blocks to applications, and leave the data placement/wear-leveling responsibilities to the host. Researchers have built several domain-specific solutions using them. For example, SDF [30] employs a hardware-software co-designed approach that exposes flash channel details and delegates I/O control-plane and data-plane tasks to host applications. LOCS [48] further improves the throughput of an LSM-tree-based KV store by optimizing the scheduling and dispatching policies, considering the characteristics of access patterns of the LevelDB. RAIL [27] designs a horizontal hot-cold separation mechanism and divides dies into two groups, where user and GC writes are scheduled to different dies, and the hot/cold ratio is dynamically adjusted based on runtime monitoring. By having full control over the device, one can implement a deterministic *v-zone* using eZNS. Despite the potential architecture, it imposes too many responsibilities on the software handling tasks that are offload-able to the device with no cost, for example, wear-leveling, physical zone-to-die mapping, etc. Another challenge arises when the system consists of heterogeneous devices resulting in the overhead of managing different H/W architectures (NAND chip capacity, channel/die configuration, etc.).

**eZNS as a firmware.** One may implement eZNS solely in the SSD using the controller and firmware. This approach can exploit internal knowledge such as NAND specification, Channel/Die structure, queue length on a die, etc. Thus, it may control the interference better and outperform the software-based implementation. However, completing eZNS in one device is not future-proof, given the disaggregated systems architecture in data centers. The software-based solution can build an eZNS-based system spanning multiple devices enabling elastic capacity scaling, load-aware allocation, high availability, and more.

## 7 Conclusion

This paper presents an in-depth study on understanding the characteristics of a commodity ZNS SSD. Then, we propose eZNS, realizing an elastic zoned view via *v-zone*, providing a flexible zone scaling interface transparent to the application that maxes out the device capability, and ensuring a fair bandwidth share between zones. We demonstrate significant performance and fairness improvements using eZNS over various scenarios.
